Artist's enhancement of scanning electron microscopy: C albicans 24 hours posttreatment with butoconazole nitrate.*

When you diagnose vulvovaginal candidiasis (VVC)

FEMSTAT® Prefill (butoconazole nitrate) Vaginal Cream 2% is clinically effective against a broad spectrum of important pathogens, including *Candida albicans* and other *Candida* species, such as *C tropicalis*.

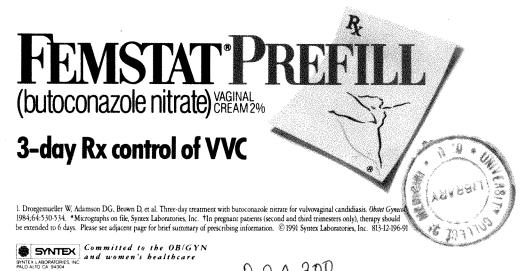

Artist's enhancement of scanning electron microscopy: C albicans one week posttreatment with butoconazole nitrate.*

Prescribe the efficacy of 3-day therapy⁺

FEMSTAT achieves a microbiological cure rate of 95% with the original 3-day therapy¹ that is not confirmed to be associated with flu-like symptoms. The most common complaint with the use of FEMSTAT in clinical trials was vulvar/vaginal burning (2.3%).

P 24,300

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS. Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION

Federal law prohibits dispensing without prescription.

YOUR PATIENTS COUNT ON YOU FOR ANSWERS...

Here are two "must-have" resources to help you explain the mysteries of childbirth to your patients. Using dramatic full-color photos and ultrasound scans, these atlases provide step-by-step coverage of fetal development and childbirth.

The role of repeat glucose tolerance tests in the diagnosis of gestational diabetes

787

Ran Neiger, MD, and Donald R. Coustan, MD Providence, Rhode Island

The finding of one abnormal value on the glucose tolerance test in pregnancy denotes a significant risk for the development of gestational diabetes.

Atrial natriuretic peptide: A vasodilator of the fetoplacental circulation?

791

John C.P. Kingdom, MB, Greg Ryan, MB, Martin J. Whittle, MD, Margaret B. McNay, MB, Adrian W. Bowman, PhD, Jackie Doyle, HND, and John M.C. Connell, MD Glasgow, Scotland

Fetal atrial natriuretic peptide levels increased in response to intravascular transfusion, but showed no significant relationship to umbilical artery Doppler echocardiographic systolic/diastolic ratios after the procedure.

Enhanced endothelium-derived relaxing factor activity in pregnant, spontaneously hypertensive rats

801

Robert A. Ahokas, PhD, Brian M. Mercer, MD, and Baha M. Sibai, MD Memphis, Tennessee

Increased basal endothelium-derived relaxing factor activity may be responsible for pregnancy vasodilation and the fall in blood pressure in spontaneously hypertensive rats.

Insignificant transfer of glyburide occurs across the human placenta

807

Byron D. Elliott, MD, Oded Langer, MD, Steve Schenker, MD, and Raymond F. Johnson, BS San Antonio, Texas

The insignificant maternal-to-fetal transfer of the oral hypoglycemic agent glyburide is demonstrated with the single-cotyledon human placental model.

Neutrophil attractant/activating peptide-1/interleukin-8 in term and preterm parturition

813

Roberto Romero, MD, Miroslav Ceska, PhD, Cecilia Avila, MD, Moshe Mazor, MD, Ernesto Behnke, MD, and Ivan Lindley, PhD

New Haven, Connecticut, Santiago, Chile, and Vienna, Austria

Amniotic fluid concentrations of neutrophil activating peptide-1/interleukin-8 are elevated in women with microbial invasion of the amniotic cavity and in women with spontaneous term and preterm labor.

Amniotic fluid white blood cell count: A rapid and simple test to diagnose microbial invasion of the amniotic cavity and predict preterm delivery

821

Roberto Romero, MD, Ruben Quintero, MD, Jose Nores, MD, Cecilia Avila, MD, Moshe Mazor, MD, Shuichi Hanaoka, MD, Zion Hagay, MD, Lydia Merchant, MS, and John C. Hobbins, MD

New Haven, Connecticut

Amniotic fluid white blood cell count is a rapid, sensitive, and inexpensive method for the diagnosis of microbial invasion of the amniotic cavity and is a specific method for detection of the patient at risk for preterm delivery.

CEFOTAN (cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT.)

INDICATIONS AND USAGE
Treatment: CEFOTAN is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary fract infections caused by Ecoli. Klebsiella species (including K pneumoniae), Proteus mirabilis, and Proteus sp (which may include the organisms now called Proteus vulgaris, Providencia rettgeri, and Morganella morganii).
Lower Respiratory Tract Infections caused by Streptococcus pneumoniae (formerly D pneumoniae), Staphylococcus aureus (penicillinase- and nonpenicillinase-producing strains), Haemophilus influenzae (including ampicillin-resistant strains), Klebsiella species (including K pneumoniae), E coli, Proteus mirabilis and Serratia marcescens:

Lower Respiratory Tract Infections caused by Streptococcus pneumoniae (formerly D pneumoniae), Staphylococcus aureus (penicillinase- and nonpenicillinase-producing strains). Haemophilus influenzae (including ampicillin-resistant strains), Klebsiella species (including K pneumoniae), E coli, Proteus mirabilis, and Serratia marcescens:

Skin and Skin Structure Infections caused by Staphylococcus aureus (penicillinase- and nonpenicillinase-producing strains). Staphylococcus epidermidis, Streptococcus progenes, Streptococcus species (excluding enterococci), E coli, Klebsiella pneumoniae, and Peptoscus' and Peptostreptococcus so', Synecologic Infections caused by Staphylococcus aureus (including penicillinase- and nonpenicillinase-producing strains), Staphylococcus epidermidis, Streptococcus species (excluding enterococci), So producing strains), Staphylococcus epidermidis, Streptococcus species (excluding B distasonis, B ovatus, and B thetalotaomicron), Fusobacterium species,* and gram-positive anaerobic cocci (including Peptococcus and Peptostreptococcus species) (excluding Peptococcus and Peptostreptococcus species) (excluding B distasonis, B ovatus, and B thetalotaomicron), and Clostridium species.*

Bone and Joint Infections caused by Staphylococcus aureus.*

Efficacy for this organism in this organ system was studied in tever than ten infections. Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known, however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vi

OCEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics. WARNINGS

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. It an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures. Pseudomembranous colitis has been reported with the use of cephalosporins (and other broadspectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.
Treatment with broad-spectrum antibiotics may after normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by Clostridium difficile is one primary cause of antibiotic-associated colitis.
Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be

antibiotic associated colitis.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by C difficile. Other causes should also be considered. In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity and, possibly, subsequent bleeding. Those at increased risk include patients with renal or hepatobiliary impairment or poor nutritional state, the elderly, and patients with cancer. Prothrombin time should be monitored and exogenous vitamin K administered as indicated. PRECAUTIONS

General: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

CEFOTAN should be used with caution in individuals with a history of gastrointestanal disease, particularly coditis.

Information for Patients: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

Drug Interactions: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminorlycoside.

alone, it is possible that hephrotoxicity may be potentiated in our other is used concomining which an aminoglycoside. **Drugf_aboratory Test Interactions:** A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported. **Carcinogenesis, Mutagenesis, impairment of Fertility:** Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

been permitted to evaluate satisfied by the permitted permitted by the per

500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methythiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day I/for 5 weeks. The relevance of these finidings to humans is unknown.

Usage in Prepnanery: Prepnanery Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to ceftotelan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Usage in Nursing Mothers: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when ceftotetan is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

tastromasmas symptoms occurred in 1.5% of patients, the most nequent were diarriae (1 in 50) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300). Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).

(1 in 300), alkaline prosponatase (1 in rou), and 10 patients and included rash (1 in 100) and including thypersensitivity reactions were reported in 1.2% of patients and included phlebitis at the site of injection (1 in 300).

Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300).

During postmarketing experience with CEFOTAN, agranulocytosis, anaphylactic reactions, fever, hermolytic anemia, leukopenia, prolonged prothrombin time with or without bleeding, pseudomembranous colitis, and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION

Treatment: The usual addut dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN				
Type of Infection Daily Dose Frequency and Route			Type of Infection	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM		
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM		
Severe	4 grams	2 g every 12 hours IV		
Life-Threatening	6* grams	3 g every 12 hours IV		

*Maximum daily dosage should not exceed 6 grams

Prophylaxis: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umblical cord is clamped.

Impaired Renal Function: When renal function is impaired, a reduced dosage schedule must be

employed. The following dosage guidelines may be used.

Creatinine Clearance	DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION	
mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
~10	Usual Recommended Dosane*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.

When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

Weight (kg) × (140 - age) Males: 72 × serum creatinine (mg/100 mL)

> Females: 0.9 x value for males

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

Shoulder dystocia: Should the fetus weighing ≥4000 grams be delivered 831 by cesarean section? Oded Langer, MD, Michael D. Berkus, MD, Robert W. Huff, MD, and Arnon Samueloff, MD San Antonio, Texas In diabetic women with infant birth weights of ≥4250 gm, 80% of cases of shoulder dystocia will result, whereas only 20% of cases will be identified in the nondiabetic cafegory. A five-year statewide experience with congenital diaphragmatic hernia 838 Katharine D. Wenstrom, MD, Carl P. Weiner, MD, and James W. Hanson, MD Iowa City, Iowa A 5-year statewide survey indicates that 55% of infants with isolated congenital diaphragmatic hernia survive without in utero surgery. Intrapartum ultrasonographic estimates of fetal weight by the house staff 842 Deborah N. Platek, MD, Michael Y. Divon, MD, Akolisa Anyaegbunam, MD, and Irwin R. Merkatz, MD Bronx. New York Ultrasonographic estimates of fetal weight performed by residents in a busy inner-city labor and delivery ward were evaluated. The cheek-to-cheek diameter in the ultrasonographic assessment of fetal 846 growth Jacques S. Abramowicz, MD, David M. Sherer, MD, Eli Bar-Tov, PhD, and James R. Woods, Jr., MD Rochester, New York Prospective ultrasonography of 200 appropriate-for-gestational-age fetuses showed that the cheek-to-cheek measurement correlated with and the cheek-to-cheek diameter/biparietal diameter ratio was independent of gestational age between 20 and 41 weeks. 853 Transforming growth factor- β_1 expression during placental development Lauren J. Dungy, MD, Tariq A. Siddiqi, MD, and Sohaib Khan, PhD Cincinnati, Ohio Peak expression of transforming growth factor- β_1 in human placenta near mid and late gestation may be related to inhibition of cytotrophoblastic proliferation. Multicenter randomized clinical trial of home uterine activity monitoring 858 for detection of preterm labor Susan M. Mou, MD, Shirazali G. Sunderji, MD, Stanley Gall, MD, Helen How, MD, Vinu Patel, MD, Mark Gray, MD, Herbert L. Kayne, PhD, and Michael Corwin, MD Kansas City, Missouri, Syracuse, New York, Chicago, Illinois, and Boston, Massachusetts Home uterine activity monitoring in addition to obstetric care in women at risk for preterm labor detects labor at lesser cervical dilatation, allowing prolongation of pregnancy and improved perinatal outcome.

Contents continued from page 7A

Adjunctive clindamycin therapy for preterm labor: Results of a double-blind, placebo-controlled trial

867

James A. McGregor, MDCM, Janice I. French, CNM, MS, and Kyung Seo, MD, PhD Denver, Colorado

A defined course of clindamycin was associated with prolongation of pregnancy in women treated for idiopathic labor before 33 weeks' gestation.

Fetal cardiac function in intrauterine growth retardation

876

Giuseppe Rizzo, MD, and Domenico Arduini, MD Rome, Italy

Several abnormalities of cardiac function are present in fetuses with intrauterine growth retardation. Longitudinal monitoring from diagnosis to the onset of antepartum late heart rate decelerations showed a progressive fall in cardiac output and in pulmonary and aortic peak velocities.

When do cardiovascular parameters return to their preconception values?

883

Eleanor J. Capeless, MD, and James F. Clapp, MD Burlington, Vermont

Stroke volume and end-diastolic volume remain elevated over their preconceptional baseline values in a population of breast-feeding women.

Baroreflex function in normal pregnancy

886

Line Leduc, MD, Nathan Wasserstrum, PhD, MD, Thomas Spillman, PhD, and David B. Cotton, MD Houston, Texas

Baroreflex sensitivity was increased in normal pregnancy at term; the attenuated pressor response to phenylephrine may result in part from increased baroreflex sensitivity.

Changes in immunologic parameters in normal pregnancy and spontaneous abortion

890

Marjory A. MacLean, MB, ChB, Rhoda Wilson, PhD, John A. Thomson, MD, Srinivasan Krishnamurthy, MB, ChB, and James J. Walker, MB, ChB Glasgow, Scotland

Immunologic changes occurring in normal pregnancy suggest an increased potential to respond to an immunologic challenge; in spontaneous abortion there is evidence of immunologic activation.

High plasma cellular fibronectin levels correlate with biochemical and clinical features of preeclampsia but cannot be attributed to hypertension alone

895

Robert N. Taylor, MD, PhD, William R. Crombleholme, MD, Steven A. Friedman, MD, Lynn A. Jones, MA, David C. Casal, PhD, and James M. Roberts, MD San Francisco and Sunnyvale, California

Plasma cellular fibronectin concentrations were found to be significantly higher in women with preeclampsia relative to levels in matched women with normal pregnancy and pregnant women with transient hypertension.

Margaret P. Appleton, MD, Thomas J. Kuehl, PhD, Marsha A. Raebel, PharmD, H. Ray Adams, PhD, A Knight, MD, and William R. Gold, MD Temple, Texas	Alfred B.
Phenytoin is a well-tolerated alternative to magnesium sulfate for seizure prophylaxis in pregnancy-induced hypertension.	•
Incidence and risk factors associated with abnormal postpartum glucose tolerance in women with gestational diabetes Patrick M. Catalano, MD, Kathleen M. Vargo, MD, Ira M. Bernstein, MD, and Saeid B. Amini, PhD Cleveland, Ohio, and Burlington, Vermont	914
Twenty-two percent (23/103) of women with gestational diabetes had an abnormal 2-hour 75 gm glucose tolerance test result at the postpartum visit.	
Urinary protein/creatinine ratio before and during pregnancy in women with diabetes mellitus C. Andrew Combs, MD, PhD, Bernadette C. Wheeler, MD, and John L. Kitzmiller, MD San Francisco, California	920
Large errors can occur when the protein/creatinine ratio is used to estimate 24-hour protein excretion in pregnant women with diabetes.	•
Drug abuse screening of childbearing-age women in Alabama public health clinics	924
Sherry K. George, MPA, Jan Price, MSN, John C. Hauth, MD, Doris M. Barnette, MSW, and Pete Pres Montgomery and Birmingham, Alabama	ton, BS
Urine samples from 5010 women were screened for marijuana, cocaine, opiates, amphetamines, and barbiturates; the prevalence was 11% for pregnant public patients and 15.6% for nonpregnant public patients.	1
Shoulder dystocia and birth trauma in gestational diabetes: A five-year experience	928
James D. Keller, MD, Jose A. Lopez-Zeno, MD, Sharon L. Dooley, MD, and Michael L. Socol, MD Chicago, Illinois	•
The incidence of shoulder dystocia and birth trauma in a large population of pregnancies complicated by gestational diabetes is described.	•

(Contents continued on page 10A)

Contents continued from page 9A

Administration of heparin by subcutaneous infusion with a programmable pump

931

Randall C. Floyd, MD, Kathy S. Gookin, MSN, L. Wayne Hess, MD, Rick W. Martin, MD, Keith F. Rawlinson, MD, Ramona K. Moenning, RN, and John C. Morrison, MD *Jackson, Mississippi*

The programmable external infusion pump appears to be an effective, safe method of administering heparin for indications during pregnancy.

Placental pathologic findings in preterm birth

934

C.M. Salafia, MD, C.A. Vogel, MD, A.M. Vintzileos, MD, K.F. Bantham, MD, J. Pezzullo, PhD, and L. Silberman, MD

Danbury and Farmington, Connecticut, and Providence, Rhode Island

Decidual vascular abnormality, umbilical-chorionic vasculitis, and chronic villitis were associated with preterm birth.

Transfer of aspirin across the perfused human placental cotyledon

939

Robert L. Jacobson, MD, Anthony Brewer, BS, Annie Eis, MS, Tariq A. Siddiqi, MD, and Leslie Myatt, PhD Cincinnati, Ohio

Low-dose aspirin rapidly crosses the placenta but does not affect perfusion pressure.

Report of fourteen cases of nonimmune hydrops fetalis in association with hemorrhagic endovasculitis of the placenta

945

Patricia M. Novak, DO, C. Maureen Sander, MD, S. Samuel Yang, MD, and Paul T. von Oeyen, MD Royal Oak, East Lansing, and Detroit, Michigan

Fourteen cases of nonimmune hydrops fetalis were found in connection with hemorrhagic endovasculitis; in eight of them the placental abnormality was the only associated significant pathologic condition.

Nifedipine pharmacokinetics and pharmacodynamics during the immediate postpartum period in patients with preeclampsia

951

John R. Barton, MD, Rebecca R. Prevost, PharmD, Donald A. Wilson, MD, W. David Whybrew, MS, and Baha M. Sibai, MD

Memphis, Tennessee

Oral nifedipine exhibited a shorter half-life and more rapid clearance in postpartum patients with preeclampsia compared with values reported for nonpregnant controls.

Microbiologic causes and neonatal outcomes associated with chorioamnion infection

955

Sharon L. Hillier, PhD, Marijane A. Krohn, PhD, Nancy B. Kiviat, MD, D. Heather Watts, MD, and David A. Eschenbach, MD

Seattle, Washington

Chorioamnion infection with group B streptococci, *Escherichia coli*, and anaerobes is associated with preterm birth, histologic chorioamnionitis, and increased neonatal mortality.

Contents

Incidence and prevalence of human immunodeficiency virus infection in a prenatal population undergoing routine voluntary human immunodeficiency virus screening, July 1987 to June 1990	961
Michael K. Lindsay, MD, MPH, Herbert B. Peterson, MD, Susan Willis, MSN, Barbara A. Slade, MD, J Gramling, RN, Harriet Williams, RN, and Luella Klein, MD Atlanta, Georgia	oanne
The incidence of human immunodeficiency virus infection in parturient women undergoing routine voluntary antibody screening increased 1.5 times over the 3-year study interval.	e e e
Natural killer cell cytotoxicity to herpes simplex virus-1-infected cells is not altered by pregnancy Nancy L. Eriksen, MD, Bernard Gonik, MD, and Lian S. Loo, MS Houston, Texas	965
Natural killer cell cytotoxicity to herpes simplex virus-1 infection in vitro is similar for pregnant and nonpregnant hosts.	
Systemic administration of interleukin-1 induces preterm parturition in mice	969
Roberto Romero, MD, Moshe Mazor, MD, and Boris Tartakovsky, PhD New Haven, Connecticut, and Beer Sheva and Rehovot, Israel	*
Systemic administration of interleukin-1 to pregnant mice induces preterm labor and delivery.	1
Prophylactic amnioinfusion as a treatment for oligohydramnios in laboring patients: A prospective, randomized trial	972
David B. Schrimmer, MD, Charles J. Macri, MD, and Richard H. Paul, MD Los Angeles, California	;
Prophylactic amnioinfusion significantly reduces the incidence of operative intervention because of fetal distress without affecting rates of infection in patients in labor with oligohydramnios.	
The second stage of labor: Factors influencing duration Jeanna M. Piper, MD, David R. Bolling, MD, and Edward R. Newton, MD San Antonio, Texas	976
Epidural analgesia, active-phase length, and parity were the best predictors of duration of the second stage of labor.	
A prospective study of two dosing regimens of oxytocin for the induction of labor in patients with unfavorable cervices	980
Andrew J. Satin, Capt, USAF, MC, Gary D.V. Hankins, Lt Col, USAF, MC, and Edward R. Yeomans, LUSAF, MC	t Col
Lackland Air Force Base, Texas	1
A more aggressive oxytocin protocol led to fewer induction failures and shorter	1

Do catechol estrogens participate in the initiation of labor?

984

Anjan Biswas, PhD, Anjan Chaudhury, MD, Sati C. Chattoraj, PhD, and Sidney L. Dale, PhD Boston, Massachusetts

Catechol estrogens in amniotic fluid increase as pregnancy progresses and are significantly higher in spontaneous labor at term in comparison with cesarean section not in labor.

The effect of fetal movement counting on maternal attachment to fetus

988

Magdy S. Mikhail, MD, Margaret C. Freda, EdD, RN, Ruth B. Merkatz, PhD, RN, Regina Polizzotto, MS, CNM, Evelyn Mazloom, MPH, CNM, and Irwin R. Merkatz, MD Bronx, New York

Women who counted their fetal movements had higher maternal-fetal attachment scores, as compared with those of controls.

A randomized, double-blind trial of prostaglandin E₂ gel for cervical ripening and meta-analysis

991

John Owen, MD, Carey L. Winkler, MD, Bruce A. Harris, Jr., MD, John C. Hauth, MD, and Mary C. Smith, PhD

Birmingham, Alabama

Both a double-blind trial and a meta-analysis of prostaglandin E_2 gel for cervical ripening showed no benefit with regard to cesarean section delivery rate.

Uterine rupture during trial of labor after previous cesarean section

996

Richard M. Farmer, MD, PhD, Thomas Kirschbaum, MD, Daniel Potter, Thomas H. Strong, MD, and Arnold L. Medearis, MD

Los Angeles, California

The Los Angeles County/University of Southern California Women's Hospital experience with uterine rupture in patients undergoing a trial of labor after a previous cesarean section from 1983 to 1989 was reviewed, with incidence rates, associations, and recommendations made.

Evaluation of obstetric ultrasonography at the first prenatal visit

1002

Jeffrey M. Barrett, MD, and Jennifer Brinson, RNC Lakeland, Florida

Obstetric ultrasonography at first prenatal visit had clinically pertinent findings in 36.5% of patients and was better than physical examination for pregnancy evaluation.

Patterns of uterine activity after intravaginal prostaglandin E_2 during preinduction cervical ripening

1006

Ann M. Miller, BSN, William F. Rayburn, MD, and Carl V. Smith, MD Omaha, Nebraska

Low-amplitude, high-frequency uterine contractions were observed shortly after prostaglandin E_2 was delivered intravaginally as a 2.5 mg gel or 10 mg controlled-release pessary and persisted with the pessary as high-amplitude contractions.

Contents

"Meconiumcrit" and birth asphyxia

1010

Kenneth J. Trimmer, MD, and Larry C. Gilstrap III, MD Dallas, Texas

The data from this investigation indicate that there is no correlation between "thickness" of meconium and recently reported markers of birth asphyxia.

The relationship between umbilical artery Doppler velocimetry and fetal biometry

1013

William E. Scorza, MD, Deborah Nardi, RT(R), RDMS, Anthony M. Vintzileos, MD, Alfred D. Fleming, MD, John F. Rodis, MD, and Winston A. Campbell, MD

Farmington, Connecticut

There is correlation between umbilical artery peak-systolic/end-diastolic ratio and fetal biometry; nomograms between peak-systolic/end-diastolic ratio and fetal biometric parameters can be used in patients with unknown or uncertain dates of gestation.

Risk factors for cordocentesis and fetal intravascular transfusion

1020

Carl P. Weiner, MD, Katharine D. Wenstrom, MD, Susan L. Sipes, MD, and Roger A. Williamson, MD Iowa City, Iowa

The risk of accessing the fetal umbilical circulation reflects both the indication and the vessel punctured.

Fetal blood sampling in patients undergoing elective cesarean section: A correlation with cord blood gas values obtained at delivery

1026

Aldo D. Khoury, MD, Michael L. Moretti, MD, John R. Barton, MD, David C. Shaver, MD, and Baha M. Sibai, MD

Memphis, Tennessee

Blood gas parameters obtained by cordocentesis were found to be significantly different from those in cord blood samples obtained at delivery in 18 patients with uncomplicated pregnancies undergoing elective cesarean section at term.

Amniotic fluid bilirubin and fetal hemolytic disease

1030

Joseph A. Spinnato, MD, Kathleen K. Ralston, MT (ASCP), Eileen R. Greenwell, MT (ASCP), Carolyn A. Marcell, RN, and Joseph A. Spinnato III, BS Louisville, Kentucky

Chloroform-extracted amniotic fluid ΔOD_{450} accurately predicts the severity of fetal hemolytic disease; its use should continue.

What is a low-lying placenta?

1036

Lawrence W. Oppenheimer, MD, Dan Farine, MD, J.W. Knox Ritchie, MD, Reuven M. Lewinsky, MD, Joyce Telford, RN, and Lea A. Fairbanks, MD

Toronto, Ontario, Canada

Criteria for diagnosing low-lying placenta with transvaginal ultrasonography are outlined, and their value with respect to management and prognosis is described.

(Contents continued on page 14A)

Contents continued from page 13A

Pulmonary-to-aorta diameter ratio in the normal and abnormal fetal heart

1038

Christine H. Comstock, MD, Thomas Riggs, MD, Wesley Lee, MD, and Janet Kirk, MD Royal Oak, Michigan

The ratio of the diameters of the fetal pulmonary artery to the aorta is independent of gestational age.

Transverse cerebellar diameter: A useful predictor of gestational age for fetuses with asymmetric growth retardation

1044

Wesley Lee, MD, Scott Barton, MD, Christine H. Comstock, MD, Stephanie Bajorek, RDMS, Daniel Batton, MD, and Janet S. Kirk, MD Royal Oak, Michigan

Gestational age in growth-retarded fetuses is estimated best by transverse cerebellar diameter when asymmetry between the head and abdomen is present.

Comparison of humerus length with femur length in fetuses with Down syndrome

1051

John F. Rodis, MD, Anthony M. Vintzileos, MD, Alfred D. Fleming, MD, Leslie Ciarleglio, MS, Deborah A. Nardi, RRT, RDMS, Lori Feeney, RRT, RDMS, William E. Scorza, MD, Winston A. Campbell, MD, and Charles Ingardia, MD

Farmington and Hartford, Connecticut

Second-trimester fetal humerus length was abnormally short (<5%) in 64% of cases of Down syndrome diagnosed prenatally; an abnormally short fetal humerus should prompt genetic studies (e.g., amniocentesis).

Ultrasonographic diagnosis of congenital anomalies in twins

1056

Steven R. Allen, MD, Leslie J. Gray, MD, Barbara H. Frentzen, MSN, and Amelia C. Cruz, MD Gainesville, Florida

Prenatal ultrasonography among twins diagnosed 69% of the major anomalies leading to altered perinatal management; the four-chamber view was an inadequate cardiac screen.

Does amniotic fluid index affect the accuracy of estimated fetal weight in preterm premature rupture of membranes?

1060

Julianne S. Toohey, MD, David F. Lewis, MD, James A. Harding, MD, Michael Crade, MD, Tamerou Asrat, MD, Carol A. Major, MD, Thomas J. Garite, MD, and Manuel Porto, MD Orange and Long Beach, California

Ultrasonography-estimated fetal weight in patients with preterm premature rupture of membranes appears to be accurate and independent of amniotic fluid volume.

Transcervical chorionic villus sampling and midtrimester oligohydramnios

1063

Edith Y. Cheng, MD, David A. Luthy, MD, Durlin E. Hickok, MD, Kathryn A. Hollenbach, PhD, Robert G. Resta, MS, Barry S. Mahony, MD, and Frederick W. Luthardt, PhD Seattle, Washington

First-trimester transcervical chorionic villus sampling was associated with a significantly increased risk for midtrimester oligohydramnios and its associated poor prognosis, as compared with midtrimester amniocentesis.

Contents

Intrapartum course of fetuses with isolated hypoplastic left heart syndrome

1068

G. Marc Jackson, MD, Jack Ludmir, MD, Arthur J. Castelbaum, MD, James C. Huhta, MD, and Arnold W. Cohen, MD

Philadelphia, Pennsylvania

Labor and delivery does not appear to be a high-risk situation for the fetus with hypoplastic left heart syndrome who is free of other abnormalities.

Fetal movement during labor

1073

Uma M. Reddy, MD, Lisa L. Paine, CNM, DrPH, Carolyn L. Gegor, CNM, MS, Mary Jo Johnson, MD, and Timothy R.B. Johnson, MD

Baltimore, Maryland, and Providence, Rhode Island

This study demonstrates the high association between fetal movement and contractions during labor.

Oligohydramnios: Antepartum fetal urine production and intrapartum fetal distress

1077

Lynn J. Groome, PhD, MD, John Owen, MD, Cherry L. Neely, RT, RDMS, and John C. Hauth, MD Birmingham, Alabama

Women with oligohydramnios whose infants are delivered abdominally because of fetal distress in labor have significantly lower antepartum rates of fetal urine production than do women whose fetuses have no distress in labor.

Antepartum fetal surveillance tests during sickle cell crisis

1081

Akolisa Anyaegbunam, MD, Marie-Ignace Gauthier Morel, MD, and Irwin R. Merkatz, MD Bronx, New York

Although sickle cell disease crisis is associated with a higher incidence of abnormal biophysical test results, in most patients these results revert to normal after crisis.

Maternal perception of decreased fetal movement as an indication for antepartum testing in a low-risk population

1084

Janice E. Whitty, MD, David A. Garfinkel, MD, and Michael Y. Divon, MD Bronx, New York

Fetal surveillance is indicated in low-risk patients with complaints of decreased fetal movement; additional testing of patients with normal initial evaluation may not be necessary.

Correlation of amniotic fluid index and nonstress test in patients with preterm premature rupture of membranes

1088

James A. Harding, MD, David M. Jackson, MD, David F. Lewis, MD, Carol A. Major, MD, Michael P. Nageotte, MD, and Tamerou Asrat, MD *Orange and Long Beach, California*

Nonstress test observations in the patient with preterm premature rupture of membranes can help identify clinically reduced amniotic fluid volumes.

(Contents continued on page 16A)

Contents continued from page 15A

Variable decelerations in reactive nonstress tests with decreased amniotic fluid index predict fetal compromise

1094

Iffath A. Hoskins, MD, Faith J. Frieden, MD, and Bruce K. Young, MD New York, New York

Spontaneous variable decelerations in reactive nonstress tests coupled with oligohydramnios (amniotic fluid index <5) identify fetuses at high risk for compromise.

Preterm premature rupture of membranes: Detection of infection

1099

Periclis Roussis, MD, Richard L. Rosemond, MD, Cheryl Glass, RN, BSN, and Frank H. Boehm, MD Nashville, Tennessee

A suggested protocol involving daily biophysical profile monitoring is proposed for the expectant management of patients with preterm premature rupture of the membranes.

Correlation of amniotic fluid glucose concentration and intraamniotic infection in patients with preterm labor or premature rupture of membranes

1105

Daniel W. Gauthier, MD, William J. Meyer, MD, and Andre Bieniarz, MD Chicago, Illinois

Amniotic fluid glucose concentration was significantly lower in patients with positive amniotic fluid cultures.

Rate of recurrence of preterm premature rupture of membranes in consecutive pregnancies

111

T. Asrat, MD, D.F. Lewis, MD, T.J. Garite, MD, C.A. Major, MD, M.P. Nageotte, MD, C.V. Towers, MD, D.M. Montgomery, MD, and W.A. Dorchester, PhD Orange and Long Beach, California

A retrospective analysis of 121 patients with 255 consecutive pregnancies complicated by preterm premature rupture of membranes is presented to define the rate of recurrence.

Renal pelvicalyceal dilation in antepartum pyelonephritis: Ultrasonographic findings

1115

Diane Twickler, MD, Bertis B. Little, PhD, Andrew J. Satin, MD, and Charles E.L. Brown, MD Dallas, Texas

Nephrosonography of gravid women with pyelonephritis revealed clinically significant renal pelvicalyceal dilation; renal pelvis dilation may antedate the disease.

Doppler flow velocities in single umbilical arteries

1120

Norman B. Duerbeck, MD, Marcello Pietrantoni, MD, Kathryn L. Reed, MD, Caroline F. Anderson, RDMS, and Lewis Shenker, MD

Tucson, Arizona

Doppler flow velocity ratios in single umbilical arteries were normal in 77% of cases.

Contents

Impact of prenatal testing on maternal-fetal bonding: Chorionic villus sampling versus amniocentesis

1122

N. Caccia, BSc, J.M. Johnson, MD, G.E. Robinson, MD, and T. Barna, BSc Toronto, Ontario, Canada

Maternal-fetal bonding increases significantly once the results of prenatal testing are known to be normal; this increase occurs earlier in patients undergoing chorionic villus sampling.

SPECIAL REPORT

The pathology of maternal mortality

1126

D.R. Shanklin, MD, Sheldon C. Sommers, MD, Dick A.J. Brown, MD, Shirley G. Driscoll, MD, and John Figgis Jewett, MD

Memphis, Tennessee, Los Angeles, California, and Boston, Massachusetts

Editors' note

The AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY introduces a new format for abstracts accompanying regular articles, society articles, and Current Investigation articles. Authors submitting these manuscripts to the JOURNAL should provide an abstract of no more than 150 words structured according to the following headings: Objective(s), Study Design, Results, and Conclusion(s). Exceptions to this requirement include Clinical Opinion, Current Development, case reports, and brief communications articles. Abstracts for these articles will continue to follow the standard abstract format. Please consult the Information for Authors for details.

The JOURNAL is abstracted and/or indexed in Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague, and MEDLINE.

Authorization to photocopy items for internal or personal use is granted by Mosby-Year Book, Inc., for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page per copy is paid directly to CCC, 27 Congress St., Salem, MA 01970; phone (508)744-3350. The U.S. Government retains a nonexclusive, royalty-free license in and to any copyright on articles authored by government employees. 0002-9378/91 \$00.00 + .10.

She needs PREMARIN to help prevent further bone loss

Calcium¹ and exercise are not enough to prevent postmenopausal osteoporosis, since estrogen deficiency is the primary cause.² PREMARIN is the only brand of estrogen indicated to prevent further bone loss and in a recently published study has been shown to reduce the risk of hip fractures by as much as 66%.³

Early PREMARIN therapy offers the best protection

The most significant rate of bone loss occurs in early menopause. PREMARIN can help maintain bone mass, preventing the progression of osteoporosis and its consequences.

Protection continues as long as estrogen therapy continues

Clinical studies show that within three years of menopause when therapy is withdrawn, bone loss begins again.4

PREMARIN°

(conjugated estrogens tablets)

Proven benefits for menopause and beyond

Estrogens have been reported to increase the risk of endometrial carcinoma in postmenopausal women. Estrogens should not be used in women (or men) with any of the following conditions: known or suspected 1) pregnancy, 2) breast cancer, 3) estrogendependent neoplasia, 4) undiagnosed abnormal genital bleeding, 5) active thrombophlebitis or thromboembolic disorders.

For moderate-to-severe vasomotor symptoms and for osteoporosis

PREMARIN

For atrophic vaginitis

PREMARIN'

(conjugated estrogens)

Vaginal Cream

0.625 mg/g

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)

PREMARIN® Brand of conjugated estrogens tablets, USP PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

L ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Close clinical surveillance of all women taking estrogens is important. Adequate diagnostic measures including endometrial sampling when indicated should be undertaken to rule out malignancy in all cases of undiagnosed persistent or recurring abnormal vaginal bleeding. There is currently no evidence that matural "estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic dosess.

2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

Estrogen therapy during pregnancy is associated with an increased risk of congenital defects in the reproductive organs of the male and female tetus, an increased risk of vaginal adenosis, squamous-cell dysplasia of the uterine cervix, and vaginal cancer in the female tater in life. The 1985 DES Task Force concluded that women who used DES during their pregnancies may subsequently experience an increased risk of breast cancer. However, a causal relationship is still unproven, and the observed level of risk is similar to that for a number of other breast cancer risk factors.

There is no indication for estrogen therapy during pregnancy. Estrogens are ineffective for the prevention or treatment of threatened or habitual abortion.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares urine. It contains estrone, equilin, and 17a-dihydroequilin, together with smaller amounts of 17a-estrations equilenin, and 17a-dihydroequilinin, as salts of their sultate seters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated

estrogens per gram.

INDICATIONS AND USAGE: Moderate-to-severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause and they should not be used to treat these conditions.) Prevention and management of osteoporosis (abnormally low bone mass). Atrophic vaginitis. Atrophic urethritis. Hypoestrogenism due to hypogonadism. castration or primary ovarian failure.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and

PREMARIN (conjugated estrogens) vaginal cream is murcated in the treatment of allogated Ratiosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETTUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected strogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected strogen-dependent appropriately selected patients being treated for metastatic disease. 3. Known or suspected estrogen-dependent neoplasia. 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. Estrogen replacement therapy has not been reported to increase the risk of thrombophlebitis and/or thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease.

PREMARIN Tablets and Vaginal Cream should not be used in patients hypersensitive to their ingredients. WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women taking higher than the property of the part of t

WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women laking higher doses of estrogen for prolonged time periods. The majority of studies have not shown an association with usual estrogen replacement doses. Endometrial cancer risk among estrogen users was about 4-fold or greater than in non-users, and appears dependent on treatment duration and estrogen dose. In patients on combined estrogen-progestin therapy, this risk appears to be decreased. (See PRECAUTIONS below.)

Estrogen therapy during pregnancy is associated with an increased risk of fetal congenital reproductive tract disorders.

disorders.

A 2.5-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens has been reported.

Large doses of strogens has been reported.

Large doses of strogens such as those used to treat prostate and breast cancer have been shown to increase the risk of non-fatal myboardial infarction, pulmonary embolism, and thrombophlebitis in men. This cannot necessarily be extrapolated to women. However, to avoid theoretical cardiovascular risk caused by high estrogen doses, the doses for estrogen replacement therapy should not exceed the recommended dose. Blood pressure should be monitored with estrogen use, especially if high doses are used. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: The addition of a progestin for 7 or more days of a cycle of estrogen administration reportedly lowers the incidence of endometrial hyperplasia. Studies of endometrium suggest that 10 to 13 days of progestin are needed to provide maximal endometrial maturation and elimination of hyperplastic changes. Additional risk, such as adverse effects on carbohydrate and lipid metabolism, may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing these adverse effects.

Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should

include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding and mastodynia. Pre-existing uterine leiomyomata may increase in size during estrogen use. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, or metabolic bone diseases associated with hypercalcemia.

The following drug/laboratory test interactions have been reported, some only with estrogen-progestin combinations (oral contraceptives):

1. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.
2. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by T₄ levels determined by column or by radioimmunoassay. Free T₃ resin uptake is decreased, reflecting the elevated TBG; free T₄ concentration is unaftered.
3. Impaired discose hierance

Impaired glucose tolerance.
Reduced response to metyrapone test.
Reduced serum folale concentration

Reduced serim rotate concentration.
 MUTAGENESIS AND CARCINOGENESIS: Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver PREGNANCY CATEGORY X: Estrogens should not be used during pregnancy. See CONTRAINDICATIONS and Pened Mexicology.

and Boxed Warning
NURSING MOTHERS: As a general principle, the administration of any drug to nursing mothers should be done
only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy; changes in vaginal bleeding
pattern and abnormal withdrawal bleeding or flow, breakthrough bleeding, spotting, increase in size of uterine
fibromyomata, vaginal candidiasis, change in amount of cervical secretion; lenderness or enlargement of breasts,
nausea, vomiting, abdominal cramps, bloating, cholestatic jaundice; chloasma or melasma that may persist when
drug is discontinued, erythema multiflorme, erythema nodosum, hemorrhagic eruption, loss of salp hair,
hirsulism; steepening of corneal curvature, intolerance to contact lenses; headache, migraine, dizziness, mental
depression, chorea, increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria;
adema: changes in libido.

depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema, changes in libido.

ACUTE OVERDOSAGE: May cause nausea and vomiting.

DOSAGE AND ADMINISTRATION:

PREMARIN* Brand of conjugated estrogens tablets, USP

1. Given cyclically for short-term use only. For treatment of moderate-to-severe vasomotor symptoms, atrophic vaginitis, or atrophic urethritis associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dosen and medication should be discontinued as promptly as possible. Administration should be cyclic (eg. three weeks on and one week off). Attempts to discontinue or taper medication should be made at three-to six-month intervals.

2. Given cyclically: Hypoestrogenism. Osteoporosis. Hypoestrogenism due to: Female hypogonadism—2.5 mg to 7.5 mg daily in divided doses for 20 days followed by 10 day rest period. It bleeding does not occur by the end of this period, the same dosage schedule is repeated. Female castration or primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Osteoporosis—0.625 mg daily. Administration should be cyclic (eg. three weeks on and one week off).

PREMARIN* Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-lerm use only. For Irealment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Aftempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Patients with an intact ulerus who are treated with either PREMARIN Tablets or Vaginal Cream should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

Obstetric Medicine. No Premier Solition Suite

In the Pregnant Patient + Medical Disorder equation, where do you fit in?

A pregnant patient with a medical disorder poses a unique and special challenge. You need to understand her disease and how it affects her pregnancy. You also need to recognize the physiologic signs of a normal gestation in order to best treat her overall condition.

In this premier volume of **Current Obstetric Medicine**, international authorities discuss recent developments in obstetric medicine, summarizing pertinent findings and trends from the literature published within the last two years. They also add their own critical commentary, providing new perspectives on the problems you face. Concentrating on emerging treatments and insights, the authorities focus on how these innovations affect your patients and your practice. This combination of the latest research and expert interpretation makes **Current Obstetric Medicine**, **Volume 1** a vital clinical reference.

You'll get a multidisciplinary perspective of new diagnostic techniques and therapies, such as preconception counseling and management of asthma, rhinitis, and anaphylaxis during pregnancy. A wide spectrum of conditions and problems are covered, including renal disease, postpartum thyroiditis, diabetes, and accidents. And each issue in **Current Obstetric Medicine** is discussed in terms of its clinical significance—so you can start applying the best available treatments to your patients' care immediately.

To review this outstanding resource free for 30 days, simply mail the Free Examination Certificate below or call Toll-Free 1-800-426-4545 (To speed your order, mention code "MCA-029"). If you aren't completely satisfied with its scope of information and insight, just send it back and owe nothing. It's an easy way to place yourself in the patient care equation.

Please send me Current Obstetric Medicine, Volume 1 (21178). I understand that I will pay \$59.95* plus shipping and handling if I decide to keep the book. * Resident price \$40 NAME ADDRESS CITY/STATE/ZIP TELEPHONE Wash Year Book Pat Newman 11830 Westline Industrial Drive St. Louis, MO 63146 MCA-029

When you purchase, we'll send you an automatic notice of future volumes about two months before they publish. This system was designed for your convenience and to take up as little of your time as possible. If you do not want the Current, the advance notice makes it easy for you to let us know. And if you elect to receive the new Current, you need do nothing. We will send it on publication. No worry. No wasted motion. And, of course, every Current is yours to examine free of charge for 30 days.

INFORMATION FOR AUTHORS Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors (N Engl J Med 1991;324:424-8). Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

- 1. Dr. Zuspan—manuscripts from the eastern and southeastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. J. Peter Van Dorsten, P.O. Box 34, MCV Station, Richmond, VA 23298.
- 2. Dr. Quilligan—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's suggested reviewers. When authors submit their manuscripts, they must provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. If not completed in full, it will be returned to the author for completion. The copyright statement and checklist form may be torn from the JOURNAL or photocopied for submission.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.

Previous publication. If a report by the same author(s) or some of the same authors has been previously published in any medium that deals in any respect whatsoever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article(s) or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. Two copies of a new manuscript being prepared for possible publication also must be submitted. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and nonhuman experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the

requisite authority. Human experimentation that requires local institutional approval must have this approval before the experiment is started and approval must be so indicated in the Material and Methods section of the submitted manuscript. Reports of experiments on nonhuman animals or other species must state in the Material and Methods section of the manuscript that the guidelines for the care and use of the animals approved by the local institution were followed. The type of nonhuman animals or other species used in an investigation must be named in the title, abstract, key words, and Material and Methods section of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of black-and-white glossy prints of illustrations are required. See "Color figures" and "Computer-generated figures" for special requirements. Manuscripts must be submitted in English.

Manuscripts must be typed double-spaced on one side only of 22×28 cm ($8\frac{1}{2} \times 11$ inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic

degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single-spaced sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page including key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Below the abstract, list 3 to 5 key words or short phrases for indexing purposes.

A structured abstract is required for certain types of articles and a standard abstract format is required for other types of articles; therefore the author(s) should select and prepare the appropriate abstract to be used in the submitted manuscript. This applies to both independently submitted and society manuscripts.

Structured abstract. A structured abstract, limited to 150 words, is to be used for regular articles, society articles, and Current Investigation articles; excluded are Clinical Opinion, Current Development, case report, and brief communication articles. The structured abstract is to contain the following major headings: Objective(s); Study Design; Results; and Conclusion(s). The Objective(s) reflects the purpose of the study, that is, the hypothesis that is being tested. The Study Design should include the setting for the study, the subjects (number and type), the treatment or intervention, and the type of statistical analysis. The Results include the outcome of the study and statistical significance if appropriate. The Conclusion(s) states the significance of the results.

Standard abstract. The standard abstract format is required for Clinical Opinion, Current Development, case report, and brief communication articles. The standard abstracts for Clinical Opinion and Current Development articles are to be 50 to 150 words and standard abstracts for case reports and brief communications are limited to 50 words. Even though the formal names of these four types of articles are not used, an author should determine his/her type of manuscript and prepare the appropriate standard abstract, regardless of whether it is to be submitted independently or as a part of a society's transactions.

Text. Do not hesitate to write your manuscript in the first person and active voice if they are more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

Council of Biology Editors Style Manual or the AMA's Manual of Style. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify *Material and Methods*, *Results*, and *Comment*. Authors may wish to summarize their findings in a short paragraph at the end of the *Comment* section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the Material and Methods section describe briefly (but in sufficient detail to permit other workers to repeat the study) the plan, the patients, experimental animals or other species, material, and controls, the methods and procedures utilized, and the statistical method(s) employed.

In the Results section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the *Results* section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (N Engl J Med 1991;324:424-8). Journal titles

should conform to abbreviations used in Cumulated Index Medicus.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term figure includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page if the color balance is appropriate.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For black-and-white figures, submit three sets of 3×4 inch (minimum) to 5×7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For color figures submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted unmounted with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. Color figures are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computergenerated illustrations.

Legends to figures. Legends for all figures must be typed together in numeric order double-spaced on one sheet of paper (or more if necessary) separate from the text of the manuscript. This page must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from the copyright owner and original author along with complete reference information. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for certain types of manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include standard abstract format, of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title.

If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article. The abstract must follow the structured format

Clinical Opinion. Limit of 3000 words. Include *standard abstract format* of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include standard abstract format of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name[s] and address[es] of the signer[s], and the phrase "To the Editors"). The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all cosigners." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of \$60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby-Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby-Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (1-800-325-4177, ext. 4306, or 314-453-4306).

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms must be completed and sent with each submitted manuscript. If not completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

- —The original and two copies of the manuscript are submitted.
- —The completed checklist is enclosed. The assignment of copyright signed by all authors accompanies the manuscript.
- —Human experimentation has been approved by the local institution as stated in the Material and Methods section.
- —Guidelines for the care and use of nonhuman animals or other species approved by the institution have been followed as indicated in the Material and Methods section.

 The species is named in the title, abstract, key words, and Material and Methods section.
- —The covering letter with essential information is with the manuscript.
- —All elements of the manuscript are typed in English double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
- —All pages are numbered in the following order: title page, condensation, structured or standard abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
- —Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
- —Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any coauthors that might pose a conflict of interest is described.

Previous publications

- —Enclosed with the submitted manuscript are two reprints each of articles the author and/or some of the coauthors have previously published, have submitted for possible publication, or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.
- -Similarities, differences and explanation are provided in

the covering letter that accompanies the submitted manuscript.

Reviewers

—Names and addresses of three suggested reviewers are enclosed.

Title page

- —These elements are given in the following sequence, and are typed double-spaced.
- -Title.
- —Author(s) name(s) and highest academic degree(s) are shown.
- —City(ies), state(s), and country other than United States in which the study was conducted are given.
- —The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the institutional affiliation(s) of the author(s) at the time of the study is indicated.
- -Acknowledgment of financial support is cited.
- —Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.
- —If reprints will not be available, this has been stated on the title page.
- —If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.
- —At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract and key words or short phrases

- —The abstract (structured or standard format) is typed double-spaced with required margins on page 3 headed by the title and author(s) name(s). Beneath the abstract 3 to 5 key words or short phrases are typed.
- —A structured abstract, with 150 words or less, is submitted as required for regular articles, society regular-type articles, and Current Investigation articles. The abstract contains the four required major headings: Objective(s), Study Design, Results, and Conclusion(s), each with a brief adequate presentation.
- —A standard abstract is submitted as required for Clinical Opinion and Current Development articles with 50 to 150 words and for case reports and brief communications articles with a maximum of 50 words, be they independent or society articles.

References

- -Are typed double-spaced.
- —Are numbered consecutively in the order they are cited in the text.
- —The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors have been followed.
- —Personal communications and unpublished observations are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

Figures

- —Each is numbered with an Arabic numeral and cited in numeric sequence in the text.
- —Three sets of unmounted glossy prints for black-andwhite figures are submitted, properly numbered, labeled, and top indicated on the back of each print.

- Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back and *top indicated* are submitted. None are dot matrix or photographic prints.
- —Original transparencies of *color photographs* appropriately numbered and identified and *top indicated* are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

Figure legends

- -Are provided for each figure.
- —Are numbered and typed together in numeric order on one sheet of paper (more if necessary). The page is numbered in sequence after the References page(s).

Tables

- —Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.
- -Tables are cited in numeric sequence in the text.

Levonorgestrel and ethinyl estradiol tablets-

THE OC TO START WITH BECAUSE SHE'LL STAY WITH IT

IN BRIEF:

IN SRIEF:
TRIPHASIL.** — 6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol; 7 light-green tablets containing inert ingredients are included in the 28-day regimen)—Triphasic regimen.

Indications and Usage —TRIPHASIL.** is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications— OCs should not be used in women with any of the following: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebits or thromboembolic disorders. 2. A past history of deep-vein thrombophlebits or thromboembolic disorders. 2. A past history of deep-vein thrombophlebits or thromboembolic disorders. 2. A past history of deep-vein thrombophlebits or thromboembolic disorders. 2. A past history of deep-vein thrombophlebits or thromboembolic disorders. 2. A past history of deep-vein thrombophlebits or thromboembolic disorders. 2. A past history of deep-vein thrombophlebits or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Endometrial carcinoma or other known or suspected of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected or pregnancy. Known or suspected pregnancy.

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contra-ceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

Should be strongly advised not to smoke.

Use of OCs is associated with increased risks of serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, gallbladder disease, and hypertension, although risk of serious morbidity/mortality is very small in healthy women without underlying risk factors. Morbidity/mortality risk increases significantly if other risk factors present (i.e. hypertension, hyperligidemias, obesity, diabetes). Practitioners prescribing OCs should be familiar with the following information relating to these risks. (This information is based principally on data involving OCs with higher doses of estrogen and progestogen than those commonly used today. Effect of long-term use of lower estrogen and progestogen formulations is yet to be determined.)

1. Thromboembolic Discorders and Other Vascular Problems— MyOCARDIAL INFARCTION (M), An increased risk of MI has been attributed to OC use. Risk is primarily in smokers or women with other underlying risk factors for coronary-aftery disease. (i.e. hypertension, hypercholesterolemia, morbid obesity, diabetes). Relative risk of heart attack for current OC users is estimated to be two to six; risk is very low under the age of 30. Smoking accounting for majority of excess cases. Mortality rates associated with circulatory disease increase substantially in smokers over the age of 35 and nonsmokers over the age of 40 among OC users.

OCs may compound effects of well-known risk factors, such as hypertension, diabetes, hyperligidemias, age and obesity, in particular, some progestogens decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. OCs have been shown to increase dood pressure among users (see Warnings). Similar effects on risk factors are associated with increased risk of heart disease. Use OCs with caution in women with cardiovascular disease risk factors.

THROMBOEMBOLISM. Increased risk of thromboembolic and thrombotic disease associated with OC use is wel

caution in women with cardiovascular disease risk factors.

THROMBOEMBOLMS L. Increased risk of thromboembolic and thrombotic disease associated with OC use is well established. In case control studies relative risk of users compared to non-users was 3 for first episode of superficial venous thrombosis, 4 to 11 for deep-vein thrombosis or pulmonary embolism, and 1,5 to 6 for women with predisposing conditions for venous thromboembolic disease. In cohort studies relative risk was somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. Thromboembolic disease risk duer, about 3 for new cases and about 4.5 for new cases requiring hospitalization. Thromboembolic disease risk duer, about 4.6 for every cases requiring hospitalization. Thromboembolic disease risk duer, about 4.6 for every cases requiring hospitalization. Thromboembolic disease risk duer, and the relative risk of venous thrombosis in women with predisposing conditions is twice that of women without such conditions. If feasible, discontinue OCs at least 4 weeks prior to and for 2 weeks after elective surgery of a type associated with increased risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is associated with an increased thromboembolic risk, start OCs no earlier than 4 to 6 weeks after delivery in women not breast-feeding, or a mid-trimester pregnancy termination. CEREBROVASCULAR DISEASES. OCs increase relative and attributable risks of cerebrovascular events (thrombotic stokes); in general, risk is gratest among older / 58 years), hypertensive women (thrombotic and hemorrhagic strokes), in general, risk is greatest among older (> 35 years), hypertensive women who smoke. Hypertension is a risk factor for users and nonusers, for both types of strokes, while smoking interacts to increase hemorrhagic stoke risk. DOSE-RELATED RISK OF VASCULAR DISEASE FROM OCS. A positive association has been observed between

amount of estrogen and progestogen in OCs and vascular disease risk. A decline in serum high density lipoproteins (HDL) is reported with many progestational agents. Serum HDL decline is associated with increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, net effect depends on balance achieved between doses of estrogen and progestogen and nature and absolute amount of progestogen used. Consider amount of both hormones in the choice of an OC.

The dosage regimen prescribed should contain the least amount of estrogen and progestogen compatible with a low failure rate and individual patient needs. Start new acceptors on preparations containing less than 50 mcg of estrogen.

PERSISTENCE OF RISK OF VASCULAR DISEASE. Two studies have shown persistence of vascular disease risk for ever-users of OCs. In a LI.S. study, MI risk after OC discontinuation persists for at least 9 years in women 40-49 years who had used OCs for five or more years, increased risk was not demonstrated in other age groups. In a study in Great Britian, the risk of developing cerebrovascular disease persisted for at least 6 years after OCs stopped, although excess risk was very small. Both studies used OC formulations with 50 micrograms or higher

of estrogens.

2. Estimates of Mortality from Contraceptive Use—A study using data from several sources concluded that with the exception of OC users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is less than that associated with childbirth. The possibility of increased mortality risk with age for OC users is based on data from the 1970s—but reported in 1983. However, current practice involves use of lower estrogen dose formulations combined with careful restriction of OC use to women without the various risk factors listed in this labeling.

Changes in practice and new data suggesting that cardiovascular disease risk with OCs may be less than previously observed prompted the Fertility and Maternal Health Drugs Advisory Committee to review the topic in 1989. The Committee concluded that although cardiovascular-disease risks may be increased with OC use after age 40 in healthy nonsmokers (even with newer low-dose formulations), greater potential health risks are associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if effective, acceptable contraception is not available.

The Committee concluded that the benefits of OC use by healthy nonsmoking women over 40 may outweigh the possible risks. Older women, as all women who take OCs, should use the lowest possible effective dose formulation.

formulation.

3. Carcinoma of the Reproductive Organs — Numerous epidemiological studies have looked at the incidence of breast, endometrial, ovarian and cervical cancer in women using OCs. Overwhelming evidence suggests that OC use is not associated with an increase in risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on breast cancer risk for at least a decade following long-term use. A few studies show a slightly increased relative risk of developing breast cancer, although the methodology of these studies, including differences in examination of users and nonusers, and in age at start of use, has been questioned. Some studies suggest that OC use is associated with an increased risk of cervical intraepithelial neoplasia in some populations of women. However, controversy continues about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between OC use and breast and cervical cancers, a cause and effect relationship has not been established.

relationship has not been established.

4. Hepatic Neoplasia—Benign hepatic adenomas are associated with OC use, although incidence is rare in the U.S. Indirect calculations estimate attributable risk to be in the range of 3.3 cases/100.000 for users, a risk that increases after four or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

British studies have shown an increased risk of hepatocellular carcinoma in long-term (> 8 years) OC users; these cancers are extremely rare in the U.S. and attributable risk (excess incidence) of liver cancers in OC users approaches less than one per million users.

5. Ocular Lesions — There are clinical case reports of retinal thrombosis with OC use. Discontinue OCs if there is unexplained partial or complete loss of vision, onset of proptosis or diplopia, papilledema, or retinal vascular lesions; undertake appropriate diagnostic and therapeutic measures immediately.

lesions; undertake appropriate diagnostic and therapeutic measures immediately.

6. Oral-Contraceptive Use Before or During Farty Pregnancy—Extensive epidemiological studies revealed no increased risk of birth defects when OCs used prior to pregnancy. Studies do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. OC-induced withdrawal bleeding should not be used as a pregnancy test. Do not use OCs during pregnancy to treat threatened or habitual abortion. Rule out pregnancy if two consecutive periods missed before continuing OC use. If patient has not adhered to prescribed schedule, consider pregnancy at time of first missed period. Discontinue OC if pregnancy confirmed.

7. Gallbladder Disease—Earlier studies reported an increased lifetime relative risk of gallbladder surgery in users of OCs and estrogens; more recent studies show that the relative risk of developing gallbladder disease among OC users may be minimal, which may be related to use of formulations with lower hormonal estrogen and propestogen doses.

OC users may be minimal, which may be related to use of formulations with lower hormonal estrogen and progestogen doses.

8. Carbohydrate and Lipid Metabolic Effects — OCs cause glucose intolerance in a significant percentage of users. OCs with greater than 75 µg of estrogen cause hyperinsulinism: lower estrogen doses cause less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance reffect varies with different agents). Observe prediabetic and diabetic women carefully while taking OCs. In non-diabetic women, OCs have no apparent effect on fasting blood glucose.

A small proportion of women will have persistent hypertriglyceridemia while on OCs. Changes in serum triglycerides and lipoprotein levels have been reported in OC users (see Warnings).

9. Elevated Blood Pressure — Increase in blood pressure has been reported in women on OCs; increase is more likely in older OC users and with continued use. Data show that incidence of hypertension increases with increasing quantities of progestogens.

likely in older OC users and with continued use. Data show that incidence of hypertension increases with increasing quantities of progestogens.

Encourage women with history of hypertension or hypertension-related diseases, or renal disease to use another contraceptive method. Monitor hypertensive women electing to use OCs closely, discontinue OC if significant blood pressure elevation occurs. For most women, elevated blood pressure returns to normal after OC stopped. No difference in occurrence of hypertension among ever- and never-users exists.

10. Headache — Discontinue OC and evaluate cause at onset or exacerbation of migraine, or if new pattern of headache (i.e. recurrent, persistent, severe) develops.

11. Bleeding irregularities — Breakthrough bleeding and spotting sometimes occur especially during first 3 months of use. Type and dose of progestogen may be important. Consider non-hormonal causes and take adequate diagnostic measures to rule out malignancy or pregnancy in event of breakthrough bleeding, as with any abnormal vaginal bleeding. If pathology excluded, time or a formulation change may solve the problem. In the event of amenorrhea, rule out pregnancy. Some women encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

Precautions

Precautions

1. Physical Examination and Follow Up—A complete medical history and physical examination should be taken prior to initiation or reinstitution of OCs and at least annually during use. Physical examination should be taken prior to initiation or reinstitution of OCs and at least annually during use. Physical exams should include special reference to blood pressure. breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests in case of undiagnosed, persistent or recurrent athormal vaginal bleeding, conduct appropriate diagnostic measures to rule out malignancy. Monitor women with strong family history of breast cancer or who have breast nodules with particular care 2. Lipid Disorders.—Follow women being treated for hyperlipidemias closely if they elect to use OCs. Some progestogens may elevate LDL levels and may render control of hyperlipidemias more difficult. (See Warnings) 3. Lipier Function—Discontinue OC I flaundice develops. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. Fluid Petention—OCs may cause some degree of fluid retention, Prescribe with caution, and only with careful monitoring, in patients with conditions possibly apgravated by fluid retention. 5. Emoland Disorders—I significant depression occurs stop medication and use alternate contraceptive method in attempts to determine if symptom is drug related. Observe carefully those with history of depression and stop drug if depression recurs to serious degree. 6. Contact Lenses—Otntact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding and menstrail rregularities are associated with concomitant rifampin use. A similar association, though less marked, is suggested with barbiturates, phenylbutazone, phenyton sodium, and possibly with griseofulvin, and biod components may be affected by OCs. a. Increased prothombin and fact

Information for the Patient — See Patient Package Labeling.

Adverse Reactions — An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, arterial thromboembolism; pulmonary embolism; myocardial infarction; cerebral hemorrhage; cerebral thrombosis; hypertension; gallbladder disease; hepatic adenomas or benign lives thrombosis. liver tumors.

There is evidence of an association between the following conditions and OC use, although additional

There is evidence of an association between the following conditions and OC use, although additional confirmatory studies are needed: mesenteric thrombosis; retinal thrombosis and averse reactions have been reported in patients on OCs and are believed to be drug-related nausea; vomiting, gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; amenorrhea, temporary infertility after treatment discontinued; edema, melasma which may persist, breast changes tenderness, enlargement, secretion, change in weight (increase or decrease); change in cervical erosion and secretion; diminution in lactation when given immediately postpartum; cholestatic jaundice, migraine; rash (allerigic), mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in OC users and the association is neither confirmed nor refuted: congenital anomalies; premenstrual syndrome; cataracts, optic neuritis; changes in appetite; cystitis-like syndrome, headache; nervousness; dizziness; hirsuitism; loss of scalp hair; erythema multiforme; erythema modosum; hemorrhagic eruption; vaginitis; porphyria; impaired renal function; hemolytic uremic syndrome; Budd-Chiari syndrome acne; changes in libido; colitis; sickle-cell disease; cerebral-vascular disease with mitral valve prolapse, lupus-like syndromes.

Overdosage — Serious ill effects have not been reported following acute ingestion of large doses of OCs by

valve prolapse; lugus-like syndromes.

Overdosage — Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Noncontraceptive Health Benefits — The following noncontraceptive health benefits related to OC use are supported by epidemiological studies that largely utilized OC formulations containing doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol. Effects on menses: increased menstrual cycle regularity, decreased blood loss and decreased incidence of inon-deficiency anemia; decreased incidence of dysmenorrhea. Effects related to inhibition of ovulation; decreased incidence of functional ovarian cysts; decreased incidence of ectopic pregnancies. Effects from long-term use: decreased incidence of fibroadenomas and fibrocystic disease of the breast, decreased incidence of acute pelvic inflammatory disease; decreased incidence of endometrial cancer; decreased incidence of acute pelvic inflammatory disease; decreased incidence of endometrial cancer; decreased incidence of acute pelvic inflammatory disease; decreased incidence of endometrial cancer; decreased incidence of ovarian cancer.

Dosage and Administration — For maximum contraceptive effectiveness, take TRIPHASIL* (levonorgestrel and ethinyl estradiol tablets — triphasic regimen 21- and 28-day regimens) exactly as directed and at intervals not over 24 hours.

Indices 24 hours. If the property of the place on it until after the first menstrual cycle of medication or postpartum, contra-ceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.) For full details on dosage and administration see prescribing information in package insert.

TRANSACTIONS OF THE ELEVENTH ANNUAL MEETING OF THE SOCIETY OF PERINATAL OBSTETRICIANS

The role of repeat glucose tolerance tests in the diagnosis of gestational diabetes

Ran Neiger, MD, and Donald R. Coustan, MD

Providence, Rhode Island

The diagnosis of gestational diabetes requires that two of the four 100 gm, 3-hour oral glucose tolerance test values be elevated. Our report evaluates the usefulness of repeating the oral glucose tolerance test in patients who have only one abnormal value. One hundred six patients who had abnormal results of diabetes screening tests (glucose level ≥ 130 mg/dl) and whose glucose tolerance test had one abnormal value underwent repeat glucose tolerance testing at an average of 4.6 weeks later. Thirty-six patients (34%) had two abnormal values on the repeat test and were classified as having gestational diabetes. Our results indicate that the finding of one abnormal value on a glucose tolerance test denotes a significant risk for the development of gestational diabetes. (AM J OBSTET GYNECOL 1991;165:787-90.)

Key words: Gestational diabetes, oral glucose tolerance test, plasma glucose levels

Gestational diabetes mellitus is defined as carbohydrate intolerance of variable severity with onset or first recognition during a pregnancy.1 Diagnosis and treatment of gestational diabetes may reduce perinatal mortality and morbidity.2 About half of patients whose oral glucose tolerance test (GTT) results are abnormal lack the risk factors traditionally considered to be markers for gestational diabetes.3 Therefore all pregnant women are now screened for gestational diabetes in many centers. Those whose screening tests results are abnormal are evaluated with a 3-hour, 100 gm oral GTT. The diagnosis of gestational diabetes requires at least two abnormal values on the oral GTT.

In an attempt to identify those patients whose initial oral GTT results are not diagnostic of gestational diabetes but in whom this disease may develop in a later initial oral GTT. Our hypothesis was that during the period between the two tests the glucose tolerance of some of these patients would worsen such that they would meet the criteria for gestational diabetes. Material and methods

stage of pregnancy, we investigated the results of repeat

oral GTTs in patients with one abnormal value on the

We screen all pregnant women for gestational diabetes at 24 to 28 weeks' gestation with a 1-hour, 50 gm glucose load. Our study population included women who had no history of diabetes and who had abnormal diabetes screening test results (glucose ≥130 mg/dl, plasma, hexokinase)4 and one abnormal value on the 3-hour, 100 gm oral GTT (defined as glucose values: fasting, ≥95 mg/dl; 1 hour, ≥180 mg/dl; 2 hours, ≥155 mg/dl; 3 hours, ≥140 mg/dl, plasma, hexokinase).5 We evaluated the likelihood of a diagnosis of gestational diabetes when the oral GTT was repeated approximately 1 month later. To evaluate the possibility of bias in the selection of patients for repeat testing, we also gathered data on subjects who, during the same period, had abnormal diabetes screening test results and one elevated oral GTT value but for various reasons did not have a follow-up GTT. Estimated gesta-

tional ages at the time of diabetes testing and at delivery were based on the time elapsed since the patients' last menstrual periods, unless contradicted by ultrasonographic studies. Perinatal outcome variables also were recorded. Calculations of average birth weight included only singleton infants delivered at ≥ 37 weeks' gestation. Statistical analysis was done with Student's t test for independent means, and the level of significance was considered to be $p \leq 0.05$.

Results

Our study population included 106 patients. Thirty-six of them (34%) had gestational diabetes on the repeat oral GTT. Demographic characteristics are listed in Table I. The results of and gestational age at the diabetes screening test and the time of the first and second oral GTTs are listed in Table II. To compare the degree of abnormality of the elevated first oral GTT values of these subjects, we calculated a derived value, delta, which is the increment of the abnormal plasma glucose value over its respective upper-normal limit, for both the criteria recommended by the American College of Obstetricians and Gynecologists⁶ and those used at our institution,⁵ measured in milligrams per deciliter.

The abnormality during the initial oral GTT was the fasting value in seven patients and the 1-, 2-, and 3-hour values in 14, 11, and 4 patients, respectively. Of the other 70 patients, 27 (39%) again had one abnormal value on the oral GTT (Fig. 1). The distribution of the

elevated glucose values on the first oral GTT of this group was as follows: fasting, 3 patients; 1-hour, 13 patients; 2-hour, 7 patients; 3-hour, 4 patients. In 16 of the 27 patients (59%) the abnormal glucose value occurred at the same time interval on the second oral GTT as during the initial study. The remaining 43 patients had normal values at all four time periods on repeat oral GTTs.

Three patients who had one abnormal glucose value on the initial oral GTT and again on the second one underwent a third oral GTT at 37 to 39 weeks' gestation. On the third test two patients had two abnormal values and were diagnosed as having gestational diabetes; the other again had one abnormal glucose value. Another patient, whose second oral GTT had four normal values, had a third oral GTT because of morbid obesity. The third test, done at 40 weeks' gestation, gave two abnormal glucose values.

We compared the patients who had repeat oral GTTs with a group of patients whose oral GTTs had one abnormal value but for various reasons did not have this test repeated (Fig. 1). Of these 117 patients, we were able to obtain complete records of 108 (92%). The reasons for not having the test repeated were as follows: The oral GTT result was interpreted as "normal" by the physician (64 patients); the patient refused to have the test repeated, did not keep the appointment, or did not finish the test (e.g., vomited) (10 patients); the patient was delivered before the test was repeated (11

^{*}Delta, Increment of the abnormal plasma glucose value over its respective upper-normal limit.

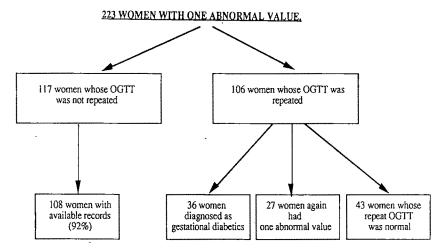

Fig. 1. Study population: 223 women with one abnormal oral GTT value.

patients); the patient was treated for gestational diabetes on the basis of one abnormal value (16 patients); reasons were unknown (7 patients). On comparison of the patients whose oral GTT was repeated with those who had only one oral GTT, there was no significant difference regarding gravidity (2.4 \pm 1.8 vs 2.4 \pm 1.5), parity (0.8 \pm 1.2 vs 0.9 \pm 1), timing and result of the diabetes screening test (27.5 \pm 1.9 vs 27.9 \pm 3.1 weeks and 148 ± 14 vs 151 ± 16 mg/dl, respectively; p = 0.2), and prepregnancy weight (106% ± 23% vs 105% ± 23% of ideal body weight). The degree of abnormality of the one elevated glucose value on the initial oral GTT also was similar (10 \pm 10 vs 12 \pm 14 mg/dl by our criteria⁵). Patients whose initial oral GTTs were repeated were younger than those who had this test only once $(27.6 \pm 5.1 \text{ vs } 29.1 \pm 5.2 \text{ years},$ p = 0.03). The first oral GTT was performed slightly but significantly later in pregnancy for those who had one oral GTT versus those whose tests were repeated $(31.9 \pm 3 \text{ vs } 30.3 \pm 2.5 \text{ weeks}, p < 0.001)$. Babies born to women whose oral GTTs were not repeated were not significantly heavier than those born to subjects who had repeat GTTs (3595 \pm 502 vs 3516 \pm 529 gm, p = 0.3).

Comment

The identification and treatment of gestational diabetes may reduce perinatal mortality and morbidity.7,8 The diagnosis of gestational diabetes is based on criteria originally proposed by O'Sullivan and Mahan,9 which include at least two abnormal glucose determinations on an oral glucose tolerance test. In our study we used the diagnostic criteria of O'Sullivan and Mahan converted for plasma glucose oxidase or hexokinase,5 which in a recent study by Sacks et al. 10 were found to be more consistent with the original criteria of O'Sullivan than were conversions proposed by the National Diabetes Data Group⁶ and endorsed by the American College of Obstetricians and Gynecologists.

The significance of a single abnormal glucose value on the oral GTT is not clear. Recent studies suggest that one abnormal value should be regarded as a pathologic finding. Langer et al.,11 using the National Diabetes Data Group criteria⁶ for normal oral GTT values, found that women with one abnormal value are at higher risk for adverse pregnancy outcomes. When untreated, such patients had a higher likelihood of large infants, as compared with patients whose oral GTT values were all normal. The infants born to patients with one abnormal value also had a significantly higher number of neonatal metabolic disorders. In another study¹² the incidence of preeclampsia or eclampsia was significantly greater in a group of patients with one abnormal oral GTT value, when compared with women whose screening tests results were normal. Tallarigo et al.13 found that even with normal oral GTT results, as defined by the National Diabetes Data Group criteria, higher 2-hour plasma glucose levels were associated with a significant increase in the incidence of macrosomia and congenital abnormalities, as well as toxemia, cesarean section, or both. Treating all patients who have one abnormal oral GTT value with a protocol of strict metabolic control was shown to be successful in reducing the incidence of large infants and metabolic problems to a level similar to that in normal control subjects.14

The data generated in this study support the hypothesis that the glucose tolerance of some patients who had one abnormal GTT value would worsen as pregnancy progressed. It is possible that patients whose gestational diabetes would have been diagnosed had the GTT been repeated make up a significant proportion of those who have large infants or whose infants have metabolic problems. If so, repeating the glucose tolerance test might have allowed for the avoidance of treatment in a significant number of patients, i.e., those whose GTT results remained normal, with the achievement of a similar good outcome for this group.

An alternative hypothesis is that the glucose tolerance test may not be a stable test with reproducible results and that patients in this study might even have had two abnormal values if the test had been repeated a day or two after its initial administration. Such a lack of stability has been demonstrated when this test was repeatedly performed on nondiabetic male volunteers. 15 A similar phenomenon was found when pregnant women were screened twice, on two successive days, with the 50 gm glucose test. 16 However, other studies demonstrated an increasing incidence of abnormal screening test results with advancing gestational age, when the same subjects were retested. 17, 18 These findings support the hypothesis that worsening glucose tolerance during the interval between the two GTTs caused the development of gestational diabetes in 34% of our patients.

Our results indicate that the presence of one abnormal value on the initial glucose tolerance test denotes a significant risk for the development of gestational diabetes. We recommend repeating the oral GTT 3 to 4 weeks after the initial study in such patients. Gestational diabetes may develop in a third of these women in the month after the first test. It is possible that the interval between tests is less important than the mere repetition of the oral GTT, a question that is unanswered in our study.

Atrial natriuretic peptide: A vasodilator of the fetoplacental circulation?

Glasgow, Scotland

Paired maternal and fetal atrial natriuretic peptide concentrations were measured in 62 percutaneous umbilical blood samplings performed principally for the assessment and treatment of rhesus isoimmunization. Pretransfusion fetal atrial natriuretic peptide levels were significantly higher than maternal atrial natriuretic peptide levels (median 117 pg/ml vs median 32 pg/ml; p < 0.001); paired pretransfusion fetal and maternal atrial natriuretic peptide samples showed a weak correlation with each other ($R^2 = 17\%$; p = 0.002). Fetal atrial natriuretic peptide levels correlated inversely with hematocrit ($R^2 = 14\%$; p = 0.003), but not with albumin or gestational age. Paired pretransfusion and posttransfusion (median = 134 pg/ml) fetal atrial natriuretic peptide levels (n = 38) showed a significant rise after transfusion (p < 0.001); this rise was related to the percentage of fetoplacental blood volume transfused ($R^2 = 33\%$; p = 0.035). In a subgroup of 26 procedures, change in fetal atrial natriuretic peptide levels was weakly correlated with transient reductions in the Doppler systolic/diastolic ratio of the umbilical artery ($R^2 = 14\%$; p = 0.07). These data support work in animals that indicate a role for atrial natriuretic peptide in the human fetus, but these data do not confirm that atrial natriuretic peptide modulates fetoplacental vascular impedance in the human fetus. (Am J Obster Gynecol. 1991;165:791-800.)

Key words: Atrial natriuretic peptide, paired maternal and fetal samples, intravascular transfusion, Doppler ultrasonography systolic/diastolic ratio, umbilical artery, middle cerebral artery, aorta

The technique of intravascular transfusion therapy for rhesus isoimmunization has transformed the prognosis for this condition, especially when the fetus has hydrops.¹ During this procedure it is possible to virtually double the estimated fetoplacental blood volume in minutes; in an adult, especially an anemic one, this process would prove disastrous. The fetus is different because additional vascular capacity is provided by the unique fetoplacental circulation, which may respond to vasoactive substances and hence may protect the fetal cardiovascular system from overload.

A putative signal between fetus and placenta in this context may be atrial natriuretic peptide, the vasodilator, natriuretic, and diuretic properties of which have been well characterized.² Studies demonstrate atrial natriuretic peptide levels in fetal blood,³⁻⁶ which increase

after intravascular transfusion, possibly in response to atrial stretch⁷; similar observations have been made with a sheep model.⁸

Specific binding sites for atrial natriuretic peptide have been identified within the placenta, 9-11 and physiologic atrial natriuretic peptide levels have been shown to reduce the vasoconstrictive effect of angiotensin II, 12 suggesting that fetal atrial natriuretic peptide (presumably released from the fetal heart) may have an endocrine action within the fetoplacental vasculature.

The circulatory adaptive events after transfusion of the fetus have been studied by several investigators using Doppler ultrasonography on the basis that the peak systolic—end-diastolic flow velocity ratio may reflect downstream vascular impedance.¹³ Umbilical arterial systolic/diastolic ratios have been shown to fall I hour after transfusion,¹⁴ and serial measurements of the pulsatility index from the umbilical artery and fetal vessels have demonstrated transient changes consistent with a reduction in downstream impedance.^{15, 16} Others, however, have not found such changes.¹⁷

The purpose of this study was to extend our original observations⁴ on the physiology of fetal atrial natriuretic peptide, in particular to examine the possible relationship between changes in fetal atrial natriuretic peptide levels and alterations in fetoplacental Doppler

ultrasonographic waveform indexes after intravascular transfusion.

Material and methods

Patient population. Thirty pregnancies were studied through 62 procedures. Of these, 27 women underwent percutaneous umbilical blood sampling for the assessment and treatment of red blood cell isoimmunization. Fourteen of the pregnancies provided serial data because of repeated transfusions. Doppler ultrasonographic studies were performed in association with 26 transfusions given to 10 of these patients. All fetuses were structurally and karyotypically normal.

Three additional women who underwent percutaneous umbilical blood sampling for fetal karyotype determination were included because their fetuses were structurally normal and had normal results of chromosomal analyses.

Collection of fetal blood samples. The ethics committee approved the study. Small samples of fetal blood (1 ml each) were initially routinely withdrawn for hematocrit, total protein, albumin, and karyotype determination with a 20-gauge spinal needle and needle guide under ultrasonographic guidance. All blood samples were taken from the umbilical vein, usually at the cord root. The purity of the fetal blood sample was checked against a maternal sample by determination of mean red blood cell volume (Chanelyzer, Coulter Electronics, Harpendon, Hertfordshire, England). An additional 1 ml of blood was taken at this point for radioimmunoassay of atrial natriuretic peptide; 1 ml of the maternal sample was used for comparison. Vecuronium bromide (0.2 to 0.4 mg) was used to paralyze the fetus before transfusion in 8 of 26 transfusions in the Doppler ultrasonography study group.

The volume of blood to be transfused was calculated on the basis of hematocrit, gestational age, and donor blood hematocrit, ^{18, 19} and included the volume to be withdrawn as samples (usually 3 to 5 ml). An additional sample to measure atrial natriuretic peptide levels was taken at the time of routine determination of posttransfusion hematocrit. A sample of donor blood was collected for measurement of atrial natriuretic peptide levels in 20 cases. Small (0.1 ml) capillary samples of donor and fetal (pretransfusion and posttransfusion) blood were obtained in 12 cases to determine pH and Po₂.

Radioimmunoassay for atrial natriuretic peptide. The samples were collected into tubes containing ethylenediaminetetraacetic acid and aprotinin on ice, separated by using a chilled centrifuge within 30 minutes, and stored at -20° C before analysis. We used the method we previously reported.²⁰ The plasma samples were initially preextracted; recovery of atrial natriuretic peptide was checked by the addition of iodine 125–

labeled atrial natriuretic peptide to control plasma and found to be >85% in each batch. The dried extracts were reconstituted in buffer, and atrial natriuretic peptide was determined by using a rabbit anti-atrial natriuretic peptide antibody. The interbatch coefficient of variation was <10%.

Measurement of fetoplacental Doppler waveforms. Measurements of the systolic-diastolic flow velocity ratios from the umbilical artery, aorta, and middle cerebral artery were obtained in a subgroup of 26 transfusions in 10 cases. Measurements were taken before transfusion (t = 0), and within 15 minutes (t = 1), at 6 hours (t = 2), and at 24 hours (t = 3) after transfusion. All measurements were taken by a single observer (G.R.) with a 3.5 MHz curvilinear probe with integralpulsed Doppler ultrasonography, color mapping, and M-mode capabilities (Spectra, Diasonics-Sonotron, Bedford, England). The high pass filter was set at 50 Hz. The technique of Mari et al.21 was used to locate the optimal signal from the middle cerebral artery, and we attempted to obtain an angle of insonation of <55 degrees for all aortic readings. In the absence of fetal breathing or movement, six consecutive waveforms were used to calculate the mean systolic/diastolic ratio at each site and the fetal heart rate.

Statistical analysis. Maternal and fetal pretransfusion and posttransfusion atrial natriuretic peptide levels were skewed, as is illustrated by the median, interquartile range, and limits of distribution (Fig. 1). A log (e) transformation allowed the atrial natriuretic peptide data to be adequately approximated by a normal distribution. Paired Student's *t* tests were used to compare differences between maternal and fetal atrial natriuretic peptide levels and fetal atrial natriuretic peptide levels before and after transfusion.

The factors influencing pretransfusion fetal atrial natriuretic peptide levels were determined by multiple regression analysis. Those variables considered to influence the change in fetal atrial natriuretic peptide levels after transfusion were analyzed in a similar manner. Relationships between other continuous variables were examined by simple linear regression and correlation. The results of these analyses are presented in terms of both R^2 and p values.

A summary (quadratic) measures analysis²² was used to analyze serial data (either heart rate or Doppler ultrasonographic systolic/diastolic ratio measurements) from each patient. In contrast to the frequently used method of comparing grouped data between individual time points, the summary measures method treats the subject (in this case each transfused fetus) as the basic unit, deriving a single number that summarized its response, the significance of which is examined with an unpaired Student t test. This method has distinct advantages in comparison with analysis of grouped data.²²

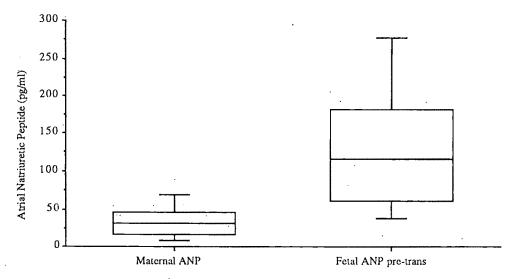

Fig. 1. Box plot of median, interquartile range, and limits of distribution of maternal and fetal pretransfusion atrial natriuretic peptide (ANP).

Our study tested the hypothesis that fetal atrial natriuretic peptide levels would rise so rapidly in response to intravascular transfusion that any effect of atrial natriuretic peptide on Doppler ultrasonographic waveforms would likely be maximal by 15 minutes and, from data with the sheep model,8 fetal atrial natriuretic peptide levels (and by implication their effects within the fetoplacental circulation) would have returned to basal levels ≤ 6 hours. An increase in circulating fetal atrial natriuretic peptide levels would be expected to facilitate blood flow; this should be represented by a reduction in observed Doppler ultrasonographic systolic/diastolic ratio. Thus a summary measure of initial reduction, followed by recovery in waveform systolic/diastolic ratio between t = 0 and t = 2 would describe the changes in systolic/diastolic ratios over time that might relate to the time course of atrial natriuretic peptide in the fetoplacental circulation. This is illustrated in Fig. 2. The significance of each derived summary measure (for heart rate and each of the three vessels studied) was examined by unpaired Student's t test.

Results

Maternal and fetal pretransfusion atrial natriuretic peptide. The plasma atrial natriuretic peptide levels results for paired maternal and fetal pretransfusion samples (n = 62) are shown in Fig. 1. Fetal atrial natriuretic peptide pretransfusion levels were significantly greater than (p < 0.001) and weakly correlated with paired maternal atrial natriuretic peptide levels (Fig. 3): $R^2 = 17\%$; p = 0.002).

Gestational age, total protein, albumin, and hematocrit were examined by multiple regression analysis to determine their independent influences on fetal atrial natriuretic peptide pretransfusion levels. Hematocrit

the most dominant variable $(R^2 = 14\%)$; p = 0.003), as is shown in Fig. 4. There was no evidence of a relationship between fetal atrial natriuretic peptide pretransfusion levels and either gestational age or total protein, whereas the relationship with fetal albumin was close to significant (p = 0.07). Among the 26 transfusions in the Doppler ultrasonography group, there was no relationship between pretransfusion atrial natriuretic peptide levels and pretransfusion heart rate (p = 0.82).

Change in fetal atrial natriuretic peptide after transfusion. The paired pretransfusion and posttransfusion fetal atrial natriuretic peptide levels are shown individually in Fig. 5 (n = 38). Fetal atrial natriuretic peptide levels increased after transfusion in most instances (median posttransfusion atrial natriuretic peptide level = 134 pg/ml), and this increase was highly significant (paired Student's t test p < 0.001). Atrial natriuretic peptide was undetectable (<3 pg/ml) in donor blood (n = 20).

Several factors thought to potentially influence the change in atrial natriuretic peptide levels after transfusion (log posttransfusion atrial natriuretic peptidelog pretransfusion atrial natriuretic peptide), such as volume of blood transfused, change in hematocrit, percentage of fetoplacental blood volume transfused, and pretransfusion atrial natriuretic peptide, were examined by multiple regression analysis, which demonstrated significant and independent relationships between change in fetal atrial natriuretic peptide levels and (I) the percentage of fetoplacental blood volume transfused ($R^2 = 33\%$; p = 0.035) and (2) pretransfusion fetal atrial natriuretic peptide levels ($R^2 = 13\%$; p = 0.01).

Donor blood was significantly acidotic (mean pH

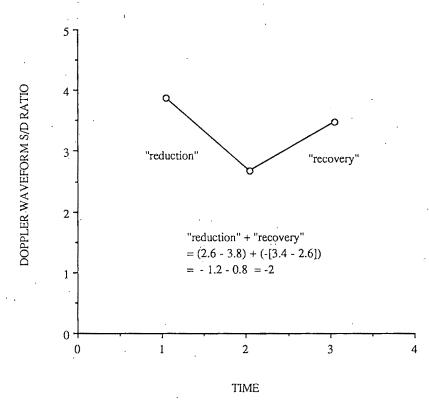

Fig. 2. Calculation of summary measure of change in waveform systolic/diastolic (S/D) ratio between three time points. Calculation is chosen to give a negative value for a response characterized by an initial reduction that is followed by a recovery.

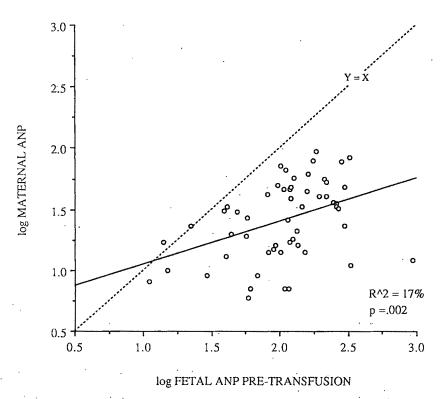

Fig. 3. Relationship between maternal and fetal pretransfusion atrial natriuretic peptide values. Note all but two lie below Y = X line, indicating that fetal atrial natriuretic peptide (ANP) levels are higher than paired maternal levels. *Continuous line* is simple regression between variables.

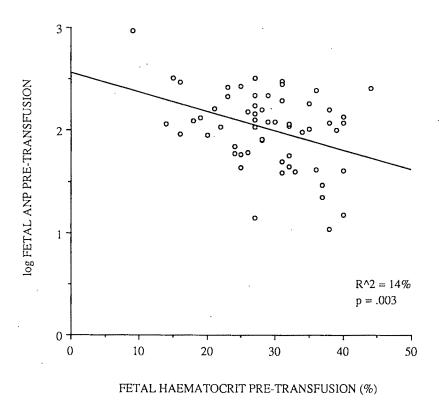

Fig. 4. Relationship between pretransfusion fetal atrial natriuretic peptide (ANP) levels and pretransfusion fetal hematocrit (p = 0.003).

6.91) compared with fetal blood pretransfusion (mean pH = 7.38; p < 0.001). In spite of transfusion (median percentage of fetoplacental blood volume given = 40%, n = 12) there was no significant change in fetal pH after this procedure (mean pH after transfusion 7.37). Similarly, the results for Po₂ showed no significant change after transfusion.

Changes in fetal heart rate and Doppler ultrasonographic waveform systolic/diastolic measurements after transfusion. The change in heart rate across each of the four time points is shown in Fig. 6, which shows an initial fall (between t = 0 and t = 1) followed by an increase (between t = 1 and t = 2). A summary measure analysis (Fig. 2) calculated for each fetus between time points 0 and 2 indicated a significant reduction and recovery in fetal heart rate after transfusion (mean change = -11.8 beats/min; unpaired Student's t test p < 0.001). This change in fetal heart rate was not associated with change in fetal atrial natriuretic peptide level ($R^2 < 1\%$; p = 0.82).

Because of the known influence of heart rate on the umbilical artery systolic/diastolic ratio (a reduction in heart rate will lower the systolic/diastolic ratio), all umbilical artery systolic/diastolic ratios were thus transformed to a standard heart rate of 140 beats/min.23 The corrected umbilical artery measurements for each fetus are shown in Fig. 7. The responses of those fetuses in whom an decrease in atrial natriuretic peptide level was observed after transfusion (n = 6) are indicated separately from the main group.

A summary measure of the corrected umbilical artery systolic/diastolic ratio and the systolic/diastolic ratios from both the middle cerebral artery and aorta for each fetus between time points 0 and 2 were derived (Fig. 2). The grouped summary measures data for each vessel studied are illustrated in Fig. 8; both the middle cerebral artery and aorta deviated significantly from baseline levels (unpaired Student's t test; middle cerebral artery, p = 0.002; aorta, p = 0.04), in contrast to the umbilical artery (p = 0.29).

The summary measure of the Doppler ultrasonographic waveform change from each vessel studied was compared with the change in fetal atrial natriuretic peptide levels (log after transfusion atrial natriuretic peptide level - log before transfusion atrial natriuretic peptide level) for each fetus. A simple regression between summary measure of the corrected umbilical artery systolic/diastolic ratio and change in fetal atrial natriuretic peptide levels (Fig. 9) is just above the conventional level of significance ($R^2 = 14\%$; p = 0.07). A similar analysis between either middle cerebral artery or aorta and change in fetal atrial natriuretic peptide levels demonstrated even weaker associations (middle cerebral artery: $R^2 = 8\%$, p = 0.21; aorta: $R^2 = 9\%$, p = 0.10), in spite of the more obvious change in waveforms in response to transfusion.

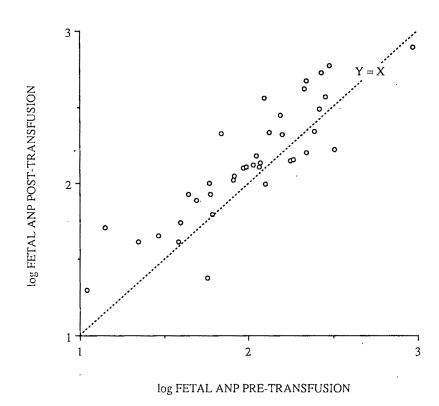

Fig. 5. Scatterplot of paired pretransfusion and posttransfusion fetal atrial natriuretic peptide (ANP) levels on a log (e) scale. Majority of data points are above the Y = X line, indicating higher posttransfusion values (p < 0.001).

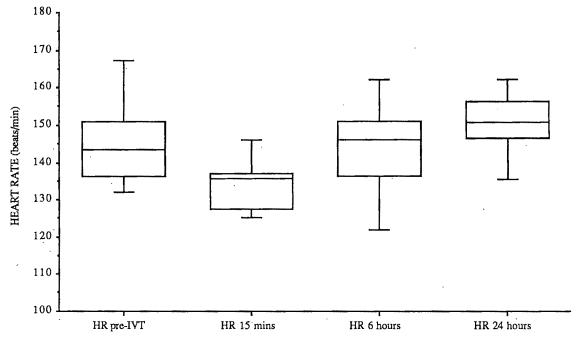

Fig. 6. Effect of intravascular transfusion (IVT) on fetal heart rate (HR) shown as grouped data. Summary measures analysis demonstrated significant changes between time points 0 and 2 (p < 0.001).

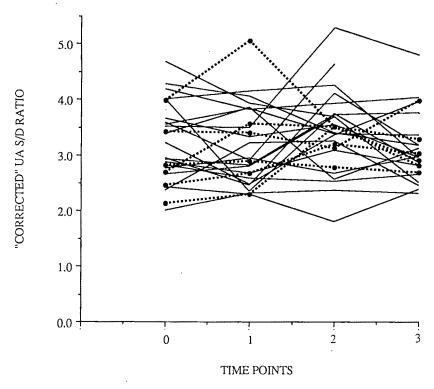

Fig. 7. Effect of intravascular transfusion on corrected umbilical artery (U/A) systolic/diastolic (S/D) ratios. -- • --, Cases in which decrease in fetal atrial natriuretic peptide levels was demonstrated after transfusion.

Comment

1

Our study provides additional information concerning the existence of atrial natriuretic peptide in the fetoplacental circulation and attempts to relate biophysical changes (as observed with Doppler ultrasonography) to an endocrine response, namely change in circulating fetal atrial natriuretic peptide levels.

Fetal atrial natriuretic peptide levels were significantly higher than paired maternal levels, suggesting independent production by the fetoplacental circulation. Furthermore, the correlation we have shown between fetal and maternal atrial natriuretic peptide levels suggests either that atrial natriuretic peptide transfers across the placenta or that the placenta itself is a source of atrial natriuretic peptide for both fetus and mother. It seems unlikely that atrial natriuretic peptide transfers across the placenta because maternal atrial natriuretic peptide levels do not rise after intravascular transfusion.5 It may be possible that the placenta itself is a source of atrial natriuretic peptide for both fetus and mother, and increased placental production of atrial natriuretic peptide during pregnancy might explain the elevation of maternal atrial natriuretic peptide levels seen toward term.24

Fetal hematocrit (and to some extent fetal albumin)

has an inverse relationship with fetal atrial natriuretic peptide, suggesting that the release of atrial natriuretic peptide increases as fetal anemia progresses. The extreme of this relationship is found in hydrops when anemia is severe, and it is interesting that experimentally induced hydrops (by using the ovine model) is associated with substantial rises in fetal atrial natriuretic peptide levels.25 The release of atrial natriuretic peptide is normally governed by atrial stretch⁷; although the raised levels of fetal atrial natriuretic peptide found in hydrops may imply increased intravascular volume space, this has not been confirmed.18

The synthesis and release mechanisms in the human fetus are likely to be different from those in the adult. All four chambers of the fetal heart seem capable of atrial natriuretic peptide synthesis,26.27 and the possibility of extracardiac synthesis (for example, in the placenta) remains. The dominant mechanism controlling the release of fetal atrial natriuretic peptide is difficult to establish from our data, and it seems likely that several factors may be involved.

Intravascular transfusion caused a significant rise in fetal atrial natriuretic peptide levels in spite of the dilutional effect of the transfused donor blood, which contained negligible amounts of atrial natriuretic pep-

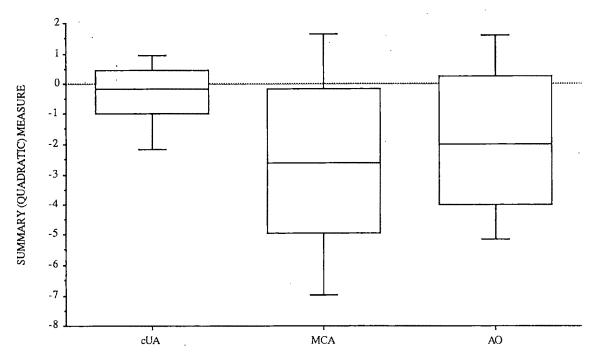

Fig. 8. Box plot of median, interquartile range, and limits of distribution for summary measures analysis of corrected umbilical artery (cUA), middle cerebral artery (MCA), and aorta (AO) waveform systolic/diastolic measurements between time points 0 and 2.

tide. It is interesting that the fetal atrial natriuretic peptide level of the baby with hydrops fell after transfusion. Fisk et al.⁶ made a similar observation, and we believe this occurs because the fetal heart has reached its maximal release rate of atrial natriuretic peptide in hydrops; thus the fall observed after transfusion is caused by dilution with donor blood.

In our study fetal atrial natriuretic peptide level responses to intravascular transfusion were significantly associated with volume transfused when expressed as a percentage change in estimated fetoplacental blood volume, suggesting that the release of atrial natriuretic peptide is related to mechanical stretch in the atria resulting from rapid intravascular transfusion along the umbilical vein. Panos et al.⁵ suggested an association between rate of transfusion and change in fetal atrial natriuretic peptide levels, although for technical reasons we believe this to be a difficult factor to measure accurately. Weiner et al.28 recently demonstrated that umbilical venous pressure rises transiently during intravascular transfusion. Umbilical venous pressure is likely to be closely related to the release of fetal atrial natriuretic peptide because it would more likely reflect change in right atrial pressure. As these authors suggest, the fall in venous pressure during transfusion might be related to vasodilatation within the placenta.

The most profound cardiovascular change in response to intravascular transfusion was a slowing of the fetal heart, which was previously described in ovine experiments²⁹ and which probably reflects a vagally mediated response to a rise in blood pressure. The change in fetal atrial natriuretic peptide level after transfusion was unrelated to this heart rate response, which is in broad agreement with recent data from a sheep model.³⁰

The relationship between change in fetal atrial natriuretic peptide levels and Doppler velocimetry of the fetal and umbilical vessels has been tested by using a summary (quadratic) measures analysis, which evaluates changes over time of the Doppler ultrasonography results. Because the fetal heart rate changes (which were not influenced by the use of vecuronium bromide) may have influenced the umbilical waveform systolic/diastolic ratios,²³ a correction was applied to a standard heart rate of 140 beats/min.

The changes in Doppler ultrasonography systolic/diastolic ratios from both the aorta and middle cerebral artery (Fig. 8) contrast those obtained from the umbilical artery. This observation may reflect a lack of innervation within the placenta, such that the fetoplacental circulation is protected from reflex-mediated changes in vascular impedance that likely operate within the fetus in response to intravascular transfusion. This phenomenon would allow relatively stable perfusion within the placenta, thereby protecting gas and nutrient transfer to the fetus.

In spite of these Doppler ultrasonographic waveform responses, there was only a weak and nonsignificant

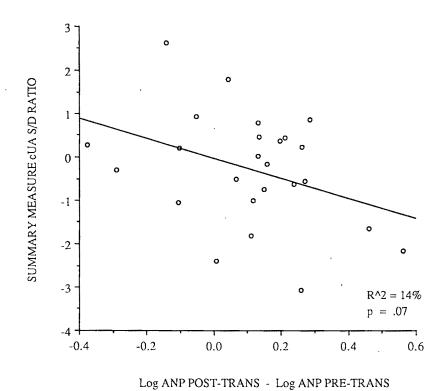

Fig. 9. Relationship between summary measure of change in corrected umbilical artery (cUA) systolic/diastolic (S/D) ratio (between time points 0 and 2) and change in fetal atrial natriuretic peptide (ANP) levels after transfusion (p = 0.07).

inverse relationship between change in atrial natriuretic peptide level and change in the umbilical artery waveform systolic/diastolic ratio. The lack of such an association is disappointing, but probably reflects the complex factors that may operate within the fetal cardiovascular system in response to intravascular transfusion. In support of this view are the observations by Brace et al.,30 who concluded from sheep experiments that the primary physiologic actions of atrial natriuretic peptide (vasodilatation and diuresis) may to a large extent be overshadowed by central cardiovascular changes. Thus it may not be surprising that we failed to demonstrate a strong relationship between elevations in fetal atrial natriuretic peptide level and implied changes in fetoplacental vascular impedance.

Another important aspect is that other vasoactive factors may operate to help the fetus cope with intravascular transfusion. Weiner and Robillard31 have shown an increase in the stable metabolite of the vasodilator prostanoid prostacyclin in fetal blood after intravascular transfusion. Moreover, this increase correlated with the rise in umbilical venous pressure, supporting the mechanism of shear-induced production of prostacyclin by the endothelial cell,32 presumably as a consequence of rapid transfusion into the umbilical vein.

The relative importance of vasoactive peptides and prostanoids (or other factors) in helping the fetus cope with intravascular transfusion remains an open question. It is hoped that future work will continue to relate biophysical data (Doppler ultrasonography or pressure measurements) to changes in putative endocrine or paracrine signals, so that we advance our understanding of fetoplacental circulation.

Enhanced endothelium-derived relaxing factor activity in pregnant, spontaneously hypertensive rats

Robert A. Ahokas, PhD, Brian M. Mercer, MD, and Baha M. Sibai, MD Memphis, Tennessee

Pregnancy is normally associated with vasodilation that, in hypertensive animals such as the spontaneously hypertensive rat, causes a profound decrease in blood pressure. To test the possibility that enhanced basal endothelium-derived relaxing factor activity has a role in the vasodilation of pregnancy, we measured the changes in mean arterial pressure and heart rate induced by N^g-monomethyl-L-arginine, a specific inhibitor of endothelium-derived relaxing factor synthesis, in conscious nonpregnant and pregnant (postmating day 20 to 21) normotensive Wistar-Kyoto and spontaneously hypertensive rats. No-monomethyl-L-arginine caused similar dose-dependent increases in mean arterial pressure in nonpregnant and pregnant Wistar-Kyoto rats, but the accompanying decrease in heart rate was significantly greater in nonpregnant rats than in pregnant ones. In the spontaneously hypertensive rats, Nª-monomethyl-L-arginine caused significantly greater dose-dependent increases in mean arterial pressure in pregnant compared with nonpregnant rats; there were no differences in the decreases in heart rate. These pressor responses were partially reversed by excess L-arginine but not D-arginine. Indomethacin had no effect on the pressor response to N^G-monomethyl-L-arginine or the depressor response to L-arginine after N^a-monomethyl-L-arginine. Therefore basal endothelium-derived relaxing factor plays a role in vascular tone and blood pressure regulation in vivo, and pregnancy may be associated with enhanced basal endothelium-derived relaxing factor activity in the hypertensive spontaneously hypertensive rats. (Am J OBSTET GYNECOL 1991;165:801-7.)

Key words: Pregnancy, vasodilation, endothelium, blood pressure, hypertension, N^c-monomethyl-L-arginine

Pregnancy, in rodents and in humans, is associated with a decrease in systemic vascular resistance. ^{1,2} Consequently, maternal blood pressure remains constant, or is moderately decreased, even though blood volume and cardiac output increase 40% to 50%. The factor(s) responsible for pregnancy vasodilation is still not known with certainty and remains the subject of intense investigation.

The vascular endothelium plays a prominent but complex role in the regulation of vascular tone and reactivity through production of a number of paracrine vasoactive substances. Since the demonstration in 1980 that vascular relaxation induced by acetylcholine was dependent on the presence of a functionally intact endothelium, numerous other agonists (e.g., bradykinin, adenosine diphosphate, histamine, and thrombin) and physical stimuli (e.g., fluid shear force and pulsatile

flow) have been shown to stimulate endothelial cell production and release of a labile endothelium-derived relaxing factor.3 Endothelium-derived relaxing factor is believed to be nitric oxide, or a nitric oxide-containing S-nitrosothiol, derived from the oxidation of the guanidino nitrogen atom of the amino acid L-arginine.5 It diffuses readily into adjacent vascular smooth muscle cells and stimulates soluble guanylate cyclase production of cyclic 3'5'-guanine monophosphate with resultant relaxation.6 Endothelium-derived relaxing factor also inhibits platelet aggregation by stimulating platelet cyclic 3'5'-guanine monophosphate production.7 Analogs of L-arginine, such as No-monomethyl-L-arginine, competitively inhibit synthesis of endothelium-derived relaxing factor and block endothelium-dependent relaxation both in vitro5. 8. 9 and in vivo. 10. 11 Furthermore, administration of NG-monomethyl-L-arginine intravenously causes a sustained increase in blood pressure with moderate bradycardia, strongly suggesting that basal endothelium-derived relaxing factor production plays a role in the regulation of vascular tone in vivo. 10-12

Recent observations that the endothelium-dependent vasodilatory response to acetylcholine was enhanced in arteries from pregnant compared with non-pregnant animals^{13, 14} have suggested the possibility that an augmentation of basal or stimulated endothelium-

Spontaneously hypertensive rats

derived relaxing factor activity may be responsible for the vasodilation of pregnancy. Furthermore, plasma levels and urinary excretion of cyclic 3'5'-guanine monophosphate are increased early in pregnancy in rats, suggesting that vascular production may be enhanced. ¹⁵ However, intravenous administration of N^c-monomethyl-L-arginine produced similar pressorresponses in term-pregnant and nonpregnant rats, suggesting that basal endothelium-derived relaxing factor production is not enhanced during pregnancy. ¹⁶

To further test the hypothesis that basal endothelium-derived relaxing factor activity is enhanced during pregnancy, we measured the pressor responses to N^Gmonomethyl-L-arginine in nonpregnant and termpregnant spontaneously hypertensive rats. These rats, a genetic model of human essential hypertension, retain the ability to vasodilate normally during pregnancy, and blood pressure falls to normotensive levels by the day before parturition.¹⁷ For comparison, we also measured the pressor responses to NG-monomethyl-Larginine in nonpregnant and term-pregnant normotensive Wistar-Kyoto rats. To test the possibility that prostaglandins may contribute to these responses, we also measured the pressor responses to N⁶monomethyl-L-arginine in indomethacin-treated nonpregnant and term-pregnant spontaneously hypertensive and Wistar-Kyoto rats.

Material and methods

Virgin female spontaneously hypertensive and Wistar-Kyoto rats (10 to 12 weeks old) were purchased from Harlan Laboratories, Inc. (Indianapolis, Ind.). The endothelium-derived relaxing factor inhibitor Nomonomethyl-L-arginine acetate was obtained from Peninsula Laboratories, Inc. (Belmont, Calif.). L-Arginine and D-arginine were obtained from Sigma Chemical Co. (St. Louis). Indomethacin trihydrate was provided by Merck, Sharp and Dohme (Rahway, N.J.). This project conforms with the "Guiding Principles in the Care

and Use of Laboratory Animals" approved by the Council of the American Physiological Society and with federal laws and regulations. The protocol used was approved by the University of Tennessee Animal Care and Use Committee.

The animals were housed in a room with temperature maintained at $22^{\circ} \pm 1^{\circ}$ C and with a 12-hour-light/12-hour-dark cycle (lights on from 6 AM to 6 PM). They were fed standard laboratory rodent chow (Ralston Purina, St. Louis) as desired with tap water to drink. Females were caged 1:1 with mature males of the same strain, and vaginal smears were checked daily in the early morning for the presence of spermatozoa. The day spermatozoa were found was designated postmating day 0. The timed-pregnant rats were subsequently housed one per cage and fed as desired until the day of experimentation (postmating day 20 or 21). Age-matched, unbred females of each strain were used for nonpregnant spontaneously hypertensive and Wistar-Kyoto rats.

Five days before experimentation, the rats were anesthetized with methoxyflurane and polyurethane catheters (Braintree Scientific, Braintree, Mass.) placed in the left carotid artery and the right external jugular vein. The catheters were tunneled subcutaneously to the back of the neck, exteriorized through a small incision between the scapulas, and fixed in place with suture and cyanoacrylate (Super Glue, B. Jadow and Sons, Inc., New York). The catheters were filled with heparinized (1000 U/ml) 0.9% saline solution and plugged with stainless steel pins. The rats were injected with penicillin G procaine and benzathine (30,000 IU per rat, intramuscularly) prophylactically.

On the day of experimentation, the rats were weighed and placed in an adjustable stainless steel holding cage designed to limit movement without causing undue stress, and the arterial catheter was connected to a pressure transducer (Statham P23Gb, Gould Electronics, Inc., Cleveland). Blood pressure was recorded

continuously with a Gould 2200S physiologic chart recorder (Gould). After blood pressure stabilization (about 1 hour), the experimental procedure was begun. In the first experiment baseline blood pressure was recorded for 5 minutes, followed by intravenous administration of cumulative doses of N^G-monomethyl-Larginine (5 to 40 mg/kg) at 5-minute intervals. Ten. minutes after the final dose, p-arginine (100 mg/kg) was administered intravenously, followed 10 minutes later by L-arginine (100 mg/kg). Mean arterial pressure was measured when blood pressure stabilized after each injection.

In the second experiment, to determine if prostaglandins play a role in the pressor response to Nomonomethyl-L-arginine, baseline blood pressure was recorded for 5 minutes after stabilization. Indomethacin (5 mg/kg) or 0.9% saline solution (untreated controls) was then administered intravenously. After I hour No-monomethyl-L-arginine (50 mg/kg) was administered intravenously, followed 30 minutes later by L-arginine (100 mg/kg). Mean arterial pressure was measured when blood pressure stabilized after each injection.

Mean arterial pressure was determined as diastolic pressure plus one third of the difference between systolic and diastolic pressure. Heart rate was read directly from the pulse pressure tracing. The maximum effect of N^G-monomethyl-L-arginine was estimated by the y intercept of the regression line of the double reciprocal plot of dose versus effect. The data are expressed as mean ± SEM. The data were analyzed by two-factor analysis of variance, and individual differences between means were determined by the least-squares means method. A value of $p \le 0.05$ was accepted as statistically significant for all analyses.

Results

Mean arterial pressure of the term-pregnant Wistar-Kyoto rats was moderately (≈35 mm Hg) but significantly lower than that of the nonpregnant Wistar-Kyoto rats (Table I). Mean arterial pressure of the term-pregnant spontaneously hypertensive rats was profoundly reduced (≈60 mm Hg) compared with that of the nonpregnant spontaneously hypertensive rats, however, and was not significantly higher than that of the nonpregnant normotensive Wistar-Kyoto rats. Pregnancy was associated with a slight, but significant, increase in heart rate in both strains of rats.

No-Monomethyl-L-arginine induced a dose-dependent increase in mean arterial pressure accompanied by a decrease in heart rate in both Wistar-Kyoto and spontaneously hypertensive rats. In the Wistar-Kyoto rats, it induced similar increases in blood pressure in both nonpregnant and pregnant rats (Fig. 1). There was no significant difference in estimated maximum effect. After the last dose of No-monomethyl-L-arginine (cumulative dose of 40 mg/kg), the decrease in heart rate was significantly greater in the nonpregnant rats compared with the pregnant Wistar-Kyoto rats (Table I, Fig. 1). In the spontaneously hypertensive rats N^cmonomethyl-L-arginine induced significantly greater increases in mean arterial pressure in the pregnant rats than in the nonpregnant rats at all doses (Fig. 2), and after the final dose the mean arterial pressure of the pregnant spontaneously hypertensive rats was not significantly lower than that of the nonpregnant spontaneously hypertensive rats before No-monomethyl-L-arginine (Table I). There were no differences between nonpregnant and pregnant spontaneously hypertensive rats in the No-monomethyl-L-arginine-induced decreases in heart rate (Fig. 2).

Excess L-arginine (100 mg/kg), but not D-arginine, partially restored mean arterial pressure to baseline levels in pregnant and nonpregnant spontaneously hypertensive and Wistar-Kyoto rats (Table I), confirming that the pressor responses to No-monomethyl-L-arginine were the result of inhibition of endothelium-derived relaxing factor synthesis from L-arginine. L-arginine had little effect on heart rate, however.

Indomethacin (5 mg/kg) pretreatment did not significantly change mean arterial pressure in either nonpregnant or pregnant Wistar-Kyoto or spontaneously

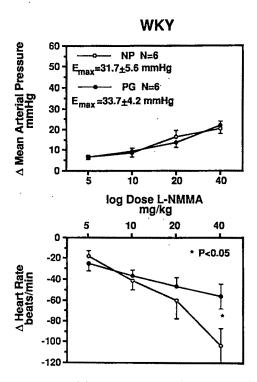

Fig. 1. Mean arterial pressure (top) and heart rate (bottom) effects of cumulative doses of N^G -monomethyl-L-arginine (L-NMMA) administered intravenously into nonpregnant and pregnant Wistar-Kyoto (WKY) rats. Data expressed as mean \pm SEM.

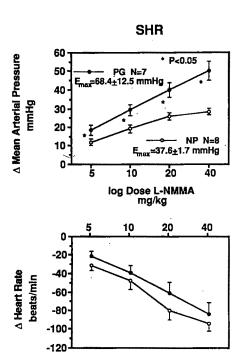

Fig. 2. Mean arterial pressure (top) and heart rate (bottom) effects of cumulative doses of N^G -monomethyl-L-arginine (L-NMMA) administered intravenously into nonpregnant and pregnant spontaneously hypertensive rats (SHR). Data expressed as mean \pm SEM.

hypertensive rats (Figs. 3 and 4). Furthermore, indomethacin pretreatment did not alter the pressor responses to N^G-monomethyl-L-arginine (50 mg/kg) or the depressor responses to L-arginine (100 mg/kg) in nonpregnant or pregnant spontaneously hypertensive or Wistar-Kyoto rats. Thus prostaglandins do not contribute to these responses.

Comment

These results confirm that rat pregnancy, like human gestation, is associated with systemic vasodilation and a decrease in maternal blood pressure. By postmating day 21, the day before expected delivery, mean arterial pressure was slightly lower and heart rate was slightly higher than in nonpregnant normotensive Wistar-Kyoto rats (Table I). They also confirm that, in the genetically hypertensive spontaneously hypertensive rat, a popular model of human essential hypertension, pregnancy has a profound antihypertensive effect. ¹⁷ By postmating day 21, blood pressure had reached normotensive levels in these rats.

The role of endothelial cell-derived autocrineparacrine substances such as prostacyclin and endothelium-derived relaxing factor in the regulation of vascular tone has been investigated extensively during the last two decades. Although vascular prostacyclin production is increased during pregnancy, there is no conclusive evidence that it is responsible for the decrease in systemic vascular resistance in the rat.18 Recent observations of enhanced endothelium-dependent relaxation responses to acetylcholine by arteries from pregnant rats¹³ and guinea pigs,¹⁴ and the observation of increased plasma levels and urinary excretion of cyclic 3'5'-guanine monophosphate, the second messenger of endothelium-derived relaxing factor-mediated vasodilation,15 has led to consideration that basal endothelium-derived relaxing factor production may be increased during pregnancy.

If basal endothelium-derived relaxing factor plays a role in the decreased vascular resistance during pregnancy, then we would expect No-monomethyl-L-arginine to cause a greater pressor response in pregnant rats compared with nonpregnant rats. In normotensive Wistar-Kyoto rats No-monomethyl-L-arginine induced similar moderate increases in mean arterial pressure in both nonpregnant and pregnant rats (Table I). Whereas these results support the hypothesis that basal endothelium-derived relaxing factor activity plays a role in vascular tone and blood pressure regulation in vivo, they do not support the hypothesis that increased endothelium-derived relaxing factor production plays a role in decreasing vascular tone during pregnancy. Our results are comparable to those of Umans et al.,16 using normotensive Sprague-Dawley rats. In their study an even higher dose of No-monomethyl-L-arginine (150 mg/kg) caused a 30 to 40 mm Hg increase

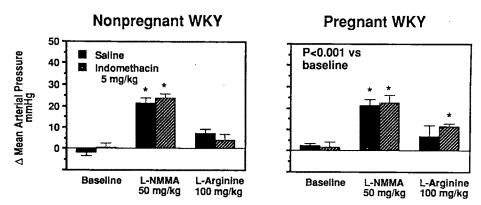

Fig. 3. Changes in mean arterial pressure (mean ± SEM) induced by N^G-monomethyl-L-arginine (L-NMMA) and L-arginine in untreated and indomethacin-treated, nonpregnant and pregnant Wistar-Kyoto (WKY) rats.

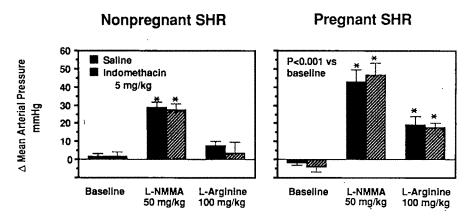

Fig. 4. Changes in mean arterial pressure (mean ± SEM) induced by N^G-monomethyl-L-arginine (L-NMMA) and L-arginine in untreated and indomethacin-treated, nonpregnant and pregnant spontaneously hypertensive rats (SHR).

in mean arterial pressure in both nonpregnant and pregnant rats. They concluded that pregnancy may not be associated with augmented basal endothelium-derived relaxing factor release and that basal and stimulated (e.g., by acetylcholine) endothelium-derived relaxing factor production may be regulated independently. Alternatively, the normotensive rat may already be in a generally vasodilated state with little need for further generalized vasodilation. The degree to which systemic vasodilation lowers blood pressure in the pregnant, normotensive rat is estimated to be very low, with decrements reported to range from 3 mm Hg19 to 17 mm Hg.20 However, in this study we observed a difference of approximately 35 mm Hg (Table I). Additional studies, including the effect of No-monomethyl-L-arginine on total periperhal resistance, are necessary to determine if basal or stimulated endothelium-derived relaxing factor plays a role in pregnancy vasodilation in normotensive rats.

The adult spontaneously hypertensive rat, on the other hand, is in a state of generalized vasoconstriction

with normal cardiac output. We have already demonstrated that pregnancy is associated with an increase in cardiac output and a decrease in the resistances of virtually all the vascular beds in the body,17 resulting in a large decrease in blood pressure (60 to 80 mm Hg) to normotensive levels by the day before delivery. Thus it was thought that this would be a good model in which to test the hypothesis that basal endothelium-derived relaxing factor activity is increased during pregnancy. Since all doses of No-monomethyl-L-arginine caused significantly greater increases in mean arterial pressure, with similar decreases in heart rate, in the pregnant compared with the nonpregnant spontaneously hypertensive rats (Table I, Fig. 2), it would appear that pregnancy may indeed augment basal endothelium-derived relaxing factor release in these rats. An alternative explanation for these results may be that vascular smooth muscle responsiveness to endothelium-derived relaxing factor is enhanced during pregnancy. This is considered unlikely, however, because preliminary results indicate that there is no difference between pregnant

and nonpregnant spontaneously hypertensive rats in the whole-body depressor response to sodium nitro-prusside (unpublished results). Sodium nitroprusside, like nitroglycerin, directly stimulates vascular smooth muscle-soluble guanylate cyclase and production of cyclic 3'5'-guanine monophosphate.²¹ Another alternative is that N^G-monomethyl-L-arginine may cause an increase in sympathetic nerve activity that may be of greater magnitude in pregnant than nonpregnant rats. Recent results in dogs have revealed a small but significant centrally mediated sympathoexcitatory effect of N^G-monomethyl-L-arginine administered intravenously.²² This possibility remains to be tested.

The fact that a molar excess of L-arginine, but not D-arginine, partially reversed the pressor responses to NG-monomethyl-L-arginine is further substantiation that the L-arginine/endothelium-derived relaxing factor pathway plays a role in vascular tone regulation in vivo. Since indomethacin did not cause any significant change in mean arterial pressure in either pregnant or nonpregnant Wistar-Kyoto or spontaneously hypertensive rats (Figs. 3 and 4), in agreement with Conrad and Colpoys, 18 we find no evidence that prostaglandins contribute to the vasodilation of pregnancy in these rats. Furthermore, since indomethacin pretreatment had no effect on the pressor response to NG-monomethyl-Larginine or the depressor response to L-arginine, neither vasoconstricting nor vasodilating prostaglandins play a role in these respective responses. Our results therefore suggest that endothelium-derived relaxing factor, not prostacyclin,23 is the antihypertensive factor of pregnancy in spontaneously hypertensive rats.

In summary, the results of this study confirm the results of others that basal endothelium-derived relaxing factor production plays a prominent role, perhaps more so than prostaglandins,24 in regulating vascular tone and blood pressure in vivo. They also support the hypothesis that pregnancy augments endothelium-derived relaxing factor activity in hypertensive spontaneously hypertensive rats. Furthermore, these results indicate that the functional integrity of the vascular endothelium, particularly with regard to the L-arginine-endothelium-derived relaxing factor pathway, may be particularly important in normal regulation of vascular tone during pregnancy in the hypertensive individual. Endothelial dysfunction and decreased production of endothelium-derived relaxing factor during pregnancy may play a role in the pathogenesis of preeclampsia.25

We thank Mr. Ed Cannon for his invaluable technical assistance and Ms. Rebecca Jorgensen for her assistance in preparation of the manuscript. We also thank Mr. Kris Arheart for his assistance in the statistical analysis of the data.

Insignificant transfer of glyburide occurs across the human placenta

Byron D. Elliott, MD, Oded Langer, MD, Steve Schenker, MD, and Raymond F. Johnson, BS

San Antonio, Texas

No data exist concerning human placental transfer of oral hypoglycemic agents during pregnancy. This study characterizes the transport of glyburide in 10 term human placentas with the single-cotyledon placental model. Serial samples were taken from both the maternal and fetal reservoirs during each 3-hour perfusion, and the percent transport and metabolism of tritiated glyburide was calculated with liquid scintillation spectrometry and high-performance liquid chromatography. Antipyrine labeled with carbon 14 was added to the perfusate solution during these experiments as a control. Virtually no transfer of glyburide occurred, and no appreciable metabolism of the drug was detected. Neither variation in the albumin concentration nor increase in the maternal glyburide levels to 100 times therapeutic concentration materially altered the rate of transport. These data show that insignificant transport of glyburide occurs across the human placenta in vitro and suggest that fetal exposure to maternally administered glyburide likewise may be insignificant. (Am J Obstet Gynecol 1991;165:807-12.)

Key words: Glyburide; diazepam; pregnancy, human; placenta

Stringent glycemic control is the main therapeutic goal in the management of the pregnant patient with diabetes. Insulin remains the drug of choice in the 10% to 60% of diabetics with failure to maintain euglycemia with diet therapy alone. Furthermore, some authors recommend the prophylactic use of insulin in all women with gestational diabetes. Although it is believed

that insulin itself does not cross the placenta, concern has recently been raised by the demonstration that insulin can readily cross the placenta as insulin-antibody complexes and possibly cause macrosomia.³

Although other modalities of management exist (e.g., oral hypoglycemic agents), their use in pregnancy is not well established. Furthermore, no study has addressed the issue of placental transfer of these drugs in humans. This has resulted in the exclusion of their use in the United States because of the fear of adverse pregnancy outcome.

Glyburide is one of the most commonly used secondgeneration sulfonylureas. Its molecular weight of 494 units of measure makes it one of the largest of the available oral hypoglycemics.⁴ Peak serum levels after a single oral dose of 5 mg occur at 4 hours and range from 112 to 360 ng/ml. Glyburide is extensively bound to albumin (98% to 99%), and metabolism occurs through hydroxylation in the liver to inactive metabolites.^{5, 6}

There is little information about the transplacental passage of oral hypoglycemic agents in humans. Disorders such as fetal anomalies, macrosomia; and neonatal hypoglycemia have been attributed to their use, 7.8 but these assumptions have not been confirmed by specific correlation with the degree of maternal-to-fetal transfer of these drugs. This study was undertaken to characterize the transport and metabolism of glyburide across the human placenta.

Methods and material

Tritiated glyburide was donated by The Upjohn Company, Kalamazoo, Mich. The purity of the substance was assured by high-performance liquid chromatographic fractionation, and identification of the peak fraction was done with the radioisotope. Stability of the compound in the perfusate solutions was tested by incubation of the compound in Krebs-Ringer buffer at pH 7.4 for 4 hours, and again the amount of parent compound was identified by joint high-performance liquid chromatography and radioimmunoassay.

Placental perfusions. The recirculating single cotyledon human placental model, as described by Brandes et al.,9 was used with minor modifications. Placentas were obtained from uncomplicated term gestations within 10 minutes of delivery. An appropriate cotyledon was chosen, and the supplying fetal artery and vein cannulated with 8 Fr. catheters. The cotyledon was then perfused with heparinized Krebs-Ringers buffer at pH 7.4. The circuit was checked for proper flow and absence of leaks. The placenta was then placed in the maternal chamber of the apparatus, and the maternal intervillous space was perfused by blunt cannulas at a flow rate of about 10 ml/min and a pressure of 1.5 cm Hg. The fetal circuit was perfused at a rate of approximately 2 ml/min and a pressure of 3.5 cm Hg. Albumin concentration in the maternal and fetal perfusates was varied between 0.2 and 2.0 gm/dl. Depending on the direction of transport being tested, the concentration of glyburide in either the maternal or fetal chamber was varied between 1000 ng/ml and 20 μg/ml (corresponding to fivefold and 100-fold peak therapeutic serum levels, respectively). Because of its poor solubility in the buffer solution, the glyburide was first dissolved into 100 µl of ethanol and then added to the perfusate. A concentration of 200 ng/ml carbon 14-antipyrine was added to either the fetal or the maternal reservoir, again depending on the direction of transport being tested in each particular experiment. The pH of both circuits was continuously monitored and maintained at

7.4 by adjusting the carbon dioxide flow and concentration in the respirators. The temperature of both systems was maintained at 37° C by automatic temperature probe. Samples of 1.0 ml were taken from both reservoirs at the beginning of the experiment, at 10-minute intervals for the first hour, and every 30 minutes thereafter. The samples were immediately centrifuged and 0.4 ml aliquots taken for scintillation spectrometry. The remaining aliquots were frozen at -30° C for future analysis.

High-performance liquid chromatographic analysis. This analysis is a modification of that described by Emilsson et al. ¹⁰ The mobile phase consisted of a 50:50 mixture of 0.01 mol/L sodium phosphate buffer/acetonitrile titrated with phosphoric acid to pH 3.5. A Beckman C8, 5 μ m, 4.6 \times 250 mm column was used. Flow rate was maintained at 1.6 ml/min with an LDC/Milton Roy Constametric III metering pump, and absorption at 225 nm was determined with an LDC/Milton Roy model 3000 spectrometer. The glyburide peak was standardized with unlabeled glyburide (Sigma Chemical Co.). With this analysis the glyburide peak occurred at 7.5 minutes.

Liquid scintillation. The Beckman LS6800 liquid scintillation spectrometer was used to determine the deteriorations per minute of both tritium and carbon 14 in each sample, corresponding to glyburide and antipyrine, respectively. Concentrations of both glyburide and antipyrine were calculated from the deteriorations per minute obtained from each sample as a percentage of that obtained in the known original concentrations.

Metabolism. The metabolism of glyburide was determined by high-performance liquid chromatographic fractionation of the initial and final maternal and final fetal samples. The deteriorations per minute of each fraction were determined by liquid scintillation spectrometry, and the metabolism was calculated as a percentage on the basis of the difference in the deteriorations per minute of the glyburide peak fractions between the initial and final samples.

Placental uptake. When each perfusion was completed, the cotyledon was injected with a solution of malachite green through the fetal arterial catheter, thus staining the perfused portion of the cotyledon. The stained portion was excised and weighed. The entire cotyledon was then homogenized in distilled water and incubated for 1 hour in a 50:50 mixture of 30% hydrogen peroxide/70% perchloric acid to clarify the homogenate. Milliliter aliquots were then taken for scintillation spectrometry. The amount of uptake per volume of placenta was calculated from the deteriorations per minute in the homogenate, with the original donor sample used as the reference.

Diazepam and glyburide share similar protein binding, partition coefficients, and molecular weights. Be-

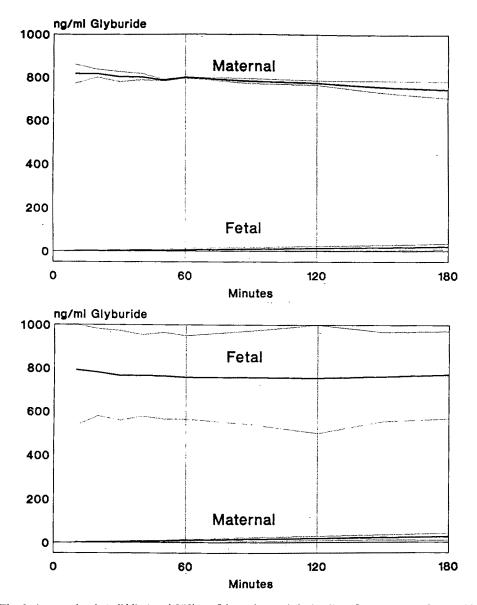

Fig. 1. Average levels (solid line) and 95% confidence interval (broken lines) for transport of glyburide in maternal-to-fetal (upper graph) and fetal-to-maternal (lower graph) directions.

cause of this, carbon 14-diazepam was added to several of the experiments in concentrations identical to those of glyburide to compare their transport. In these experiments unlabeled antipyrine was used, and its transport was determined by high-performance liquid chromatographic assay.11 Diazepam and glyburide concentrations were determined by liquid scintillation spectrometry in these experiments.

Equilibrium dialysis and partition coefficient. Equilibrium dialysis of glyburide and diazepam was performed across Spectrapore dialysis tubing with a molecular weight cutoff of 12,000 to 14,000 using Krebs-Ringer buffer with and without 2.0 gm/dl albumin to test their protein binding. A drug concentration of 1000 ng/ml was added to the buffer/albumin side, and the percent binding was determined by scintillation spectrometry after a 2-hour incubation period in a water bath at 37° C. A partition coefficient was determined by incubation and agitation in an octanol/buffer interface for 1 hour at 37° C, and again the differential concentrations were determined by scintillation spectrometry.

Statistics. The percentage of glyburide transported at 2 hours in both maternal-to-fetal and fetal-to-maternal directions was compared with the Mann-Whitney U test, and a p value of ≤ 0.05 was considered significant.

Results

The purity of the tritiated glyburide was 90%, and the compound remained stable in the Krebs-Ringer buffer during the 4-hour test period. There was vir-

tually no transport of glyburide in either the maternal-to-fetal or the fetal-to-maternal direction. The average transport at 2 hours was 0.62% (n=3) from maternal-to-fetal circuits. The fetal-to-maternal transport was similar (p=0.35) at 0.89% (n=3). The overall transport of glyburide in both the maternal-to-fetal and fetal-to-maternal direction is illustrated in Fig. 1. The maternal-to-fetal transport of glyburide achieved an average fetal concentration of 26 ng/ml at 2 hours, when the original maternal concentration was 1000 ng/ml. This maternal concentration represents three-fold to eightfold therapeutic peak levels after a 5 mg oral dose in humans.

Varying the albumin concentration of both fetal and maternal perfusates had little effect on the transport of glyburide. Increasing the glyburide concentration to 100 times therapeutic levels likewise did not alter transport appreciably. A summary of these data is given in Tables I to III. There were no appreciable levels of metabolized glyburide detected in either donor or receiver perfusates or in the placental homogenates.

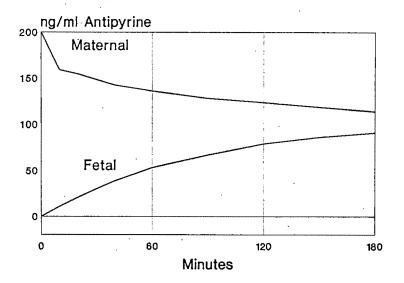

Placental uptake of glyburide ranged from 121 to 434 ng/gm placenta. This yielded a concentration of

glyburide per placental volume identical to the concentration in the perfusate solution in the receiving side of the experiment.

The observed transport of antipyrine was as expected. The antipyrine concentrations equilibrated between the maternal and fetal perfusates at approximately 120 minutes in both the maternal-to-fetal and fetal-to-maternal direction. The average maternal-to-fetal transport of both antipyrine and diazepam is illustrated in Fig. 2.

Equilibrium dialysis demonstrated both glyburide and diazepam to be 97% to 98% protein bound. Both substances yielded an octanol/buffer partition coefficient of 6.6.

The transport of diazepam in these experiments is characterized by rapid placental uptake and equilibration of fetal and maternal concentrations by 60 minutes. Maternal-to-fetal transport at 120 minutes ranges from 33% to 72%, and placental concentration is equivalent to both maternal and fetal concentration. This transport achieves an average fetal concentration of 420 ng/ml at 2 hours with the original maternal concentration of 1000 ng/ml.

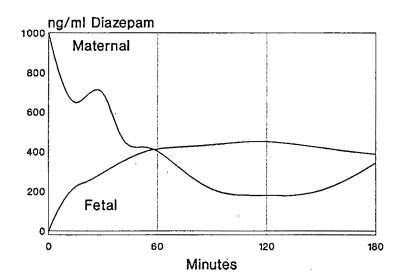

Fig. 2. Average transport of antipyrine (upper graph) and diazepam (lower graph) in maternal-to-fetal direction.

Comment

Our study is significant in that it is the first demonstration of negligible human placental transfer of glyburide. The implication from these findings is that maternally administered glyburide in pharmacologic dosages, even those greatly exceeding therapeutic levels, may not reach the fetus.

The recirculating single-cotyledon human placental model is used extensively to characterize the transport and metabolism of numerous pharmacologic agents and nutrients. 12, 13 It is well established as a safe in vitro surrogate for human placental transfer and is a desirable model because it allows study in the intact human placenta independent of any fetal metabolism. Another attribute of this system is the ability to validate each experiment individually with the addition of antipyrine. Antipyrine is transferred across the human placenta by simple diffusion in both maternal-to-fetal and fetal-to-maternal directions. With its use each experiment can be individually validated for proper transport characteristics and equilibration of antipyrine between the maternal and fetal systems.

On the basis of our study, placental transfer of substances cannot be predicted on the basis of protein binding, lipid solubility, or molecular weight alone. The comparison of the transport of glyburide and diazepam in our study demonstrates how dissimilar molecular configuration can cause a profound difference in the rate of transport of substances in spite of great similarity in the physical properties mentioned. We speculate that it is the rigidity of its tertiary structure that limits the transport of glyburide across the placental

membrane. This could be confirmed by comparing its transport and tertiary structure with those of the other sulfonylureas.

The findings in this study show (1) that glyburide does not cross the human placenta from the maternal to the fetal circulation in significant amounts, (2) that neither drug nor albumin concentration affects the rate of its transfer, (3) that glyburide is neither metabolized nor sequestered by the placenta, and (4) that the fetal-to-maternal transport of the drug is similar to the maternal-to-fetal transport; that is, it is not directionally selective and thus is suggestive of passive transfer.

Although several centers in other countries have reported the use of oral hypoglycemic agents during pregnancy,14-16 concern exists in the United States as to their possible effects on the developing fetus and newborn, on the basis of the assumption that significant transfer occurs across the placenta. These concerns have generally fallen into three categories: (1) the possible teratogenicity early in development, (2) the possible induction of fetal macrosomia by direct stimulation of insulin release from the fetal pancreas, and (3) the possibility of neonatal hypoglycemia if the newborn acquires pharmacologic levels. Our study demonstrates that glyburide does not cross the placenta in significant quantities; therefore the underlying assumption of these concerns is now brought into question. Our findings suggest the potential safety of this drug in pregnancy; however, the question of its ability to maintain adequate glycemic control remains to be answered. Previous studies have not addressed this issue.

Some studies have suggested a possible link between the use of oral hypoglycemics and fetal anomalies, fetal macrosomia, and neonatal hypoglycemia, whereas others have demonstrated no such relationship. 14-16 These aberrations are associated with poor maternal glycemic control and, in these studies, could have been the result of chronic maternal hyperglycemia rather than the effect of the agent itself. The majority of these studies are small and do not account for the level of maternal glycemic control, which could explain the conflicting results.

We have now demonstrated that glyburide does not cross the human placenta in significant amounts, so that the question of its safety from the standpoint of the fetus is greatly diminished and its use in the management of gestational diabetes becomes a possibility. We hypothesize that this agent may be a safer and more convenient alternative to insulin injections in selected

pregnant diabetic women, and we hope that our study will encourage further investigation into the use of oral hypoglycemics in pregnancy.

Neutrophil attractant/activating peptide-1/interleukin-8 in term and preterm parturition

Roberto Romero, MD,^a Miroslav Ceska, PhD,^c Cecilia Avila, MD,^a Moshe Mazor, MD,^a Ernesto Behnke, MD,^b and Ivan Lindley, PhD^c

New Haven, Connecticut, Santiago, Chile, and Vienna, Austria

The neutrophil is the leukocyte most frequently recruited into the amniotic fluid in cases of microbial invasion of the amniotic cavity. Neutrophil attractant/activating peptide-1/interleukin-8 is a newly identified cytokine that is capable of inducing selective neutrophil chemotaxis and activation. The purpose of this study was to examine the relationship between amniotic fluid concentrations of neutrophil attractant/activating peptide-1/interleukin-8, microbial invasion of the amniotic cavity, and parturition (term and preterm). Amniotic fluid neutrophil attractant/activating peptide-1/interleukin-8 was measured with an immunoassay validated for human amniotic fluid (sensitivity, 0.3 ng/ml). Fluid was obtained from women in the following groups: midtrimester (n = 38), term not in labor (n = 38), term in active labor (n = 67), and preterm labor with intact membranes (n = 62). Fluid was cultured for aerobic and anaerobic bacteria and Mycoplasma. Sterile amniotic fluid from most women in the midtrimester of pregnancy and women at term not in labor did not contain immunoreactive neutrophil attractant/activating peptide-1/interleukin-8. Microbial invasion of the amniotic cavity was associated with increased concentrations of neutrophil attractant/activating peptide-1/interleukin-8. The amniotic fluid of women with preterm labor and sterile amniotic fluid who had preterm delivery contained higher neutrophil attractant/activating peptide-1/interleukin-8 levels than did the amniotic fluid of women who responded to tocolysis and had delivery at term. Term parturition is associated with increased concentrations of neutrophil attractant/activating peptide-1/interleukin-8 in the amniotic fluid. We conclude that neutrophil attractant/activating peptide-1/interleukin-8 is part of the host response to microbial invasion of the amniotic cavity and that increased amniotic fluid availability of this cytokine occurs in term and preterm parturition. (Am J OBSTET GYNECOL 1991;165:813-20.)

Key words: Neutrophil attractant/activating peptide-1, interleukin-8, chemotaxis, chorioamnionitis, parturition, labor, prematurity, cytokines, amniotic fluid, preterm labor

Although the neutrophil is the leukocyte most frequently recruited into the amniotic fluid in cases of microbial invasion of the amniotic cavity, the mechanisms responsible for neutrophil chemotaxis in intrauterine infection have not been defined. Neutrophil chemoattractants include bacterial peptides, platelet activating factor, leukotriene B₄, and complement C5_a. Neutrophil attractant/activating peptide-1 (NAP-1)/interleukin-8 (IL-8) is a novel 8400 d cytokine that induces neutrophil chemotaxis and granule release. Originally purified from conditioned media obtained from bacterial endotoxin (lipopolysaccharide-

LPS)—stimulated human mononuclear cells,^{5. 6} NAP-1/IL-8 was subsequently isolated from lipopolysaccharide-stimulated lung macrophages,⁷ mitogen-stimulated lymphocytes, and virus-infected fibroblasts.⁸ The NAP-1/IL-8 gene is placed at position 4q12-q21 on the human genome in a gene cluster with other members of the platelet factor-4 gene superfamily.⁹ The structure and biologic functions of NAP-1/IL-8 recently were reviewed.¹⁰

The studies described in this communication were undertaken to determine the relationship between gestational age, parturition (term and preterm), microbial invasion of the amniotic cavity, and amniotic fluid concentrations of NAP-1/IL-8.

Material and methods

Study design. A cross-sectional study was constructed according to the results of amniotic fluid cultures, gestational age, and labor status. Four groups were identified for study purposes. Group 1 comprised women in the midtrimester of pregnancy (gestational age, 16 to 18 weeks) undergoing amniocentesis for genetic indications (maternal age >35 years) (n=38). Group 2

October 1991 Am J Obstet Gynecol

814 Romero et al.

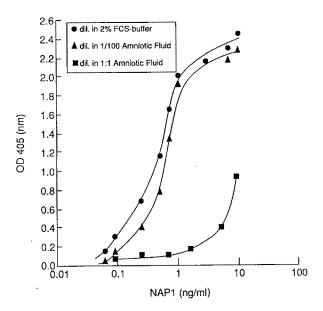

Fig. 1. Validation of immunoassay for detection of NAP-1/IL-8 in human amniotic fluid. Assay standard curve was constructed by adding increasing concentrations of human recombinant NAP-1/IL-8 to assay buffer containing 2% fetal calf serum (FCS) (circles). Poor recovery was observed when human recombinant NAP-1/IL-8 was added to pure pooled human amniotic fluid (squares). Parallelism was achieved when amniotic fluid was diluted (1:100) with assay buffer and 2% fetal calf serum (triangles). Vertical axis displays optical density whereas horizontal axis illustrates final concentrations of human recombinant NAP-1/IL-8.

was composed of women at term (38 to 39 weeks) who had amniocentesis for the assessment of fetal lung maturity before elective cesarean section (n = 38). Group 3 was made up of women in spontaneous active labor at term (38 to 41 weeks) (n = 67). These patients were subclassified according to the results of amniotic fluid culture into subgroups: subgroup 3a, women with negative amniotic fluid cultures (n = 49); subgroup 3b, women with positive amniotic fluid cultures (n = 18). Group 4 consisted of women admitted with preterm labor and intact membranes (n = 62). This group was divided into three subgroups according to amniotic fluid culture results and response to tocolysis: subgroup 4a, women with negative amniotic fluid cultures who responded to tocolysis and delivered at term (n = 25); subgroup 4b, women with negative amniotic fluid cultures and delivery of a preterm neonate in spite of tocolysis (n = 24); subgroup 4c, women with positive amniotic fluid cultures and premature delivery (n = 13).

Nitrazine, pooling, and ferning tests were performed in all women in labor to exclude rupture of membranes. Preterm labor was defined as the presence of regular uterine contractions with a frequency of at least two every 10 minutes associated with changes in the Bishop score. Ritodrine was administered intravenously as the tocolytic agent according to a protocol described else-

where by Caritis. Amniocentesis was performed before the initiation of therapy. Failure of tocolysis was diagnosed when cervical dilatation progressed beyond 5 cm or delivery occurred.

Retrieval of amniotic fluid. Amniotic fluid was retrieved by transabdominal amniocentesis. Amniocentesis for microbiologic studies is offered in our institution to all patients with the diagnosis of preterm labor. Women in active labor at term were identified by searching our obstetric data base to identify patients who underwent amniocentesis because of suspected preterm labor but who subsequently delivered a term neonate (within 12 hours of amniocentesis). The identification numbers of patients fulfilling these criteria were cross-referenced with samples stored in our amniotic fluid bank. This bank consists of aliquots of amniotic fluid that remain after clinically indicated tests are performed. For the purposes of storage in this bank, fluid was centrifuged at 200g for 10 minutes at 4° C and stored in polypropylene tubes at -70° C until assayed.

Microbiologic culture technique. Amniotic fluid was transported to the laboratory in a capped plastic syringe immediately after collection. Plating occurred within 30 minutes of collection in all cases. Fluid was cultured for aerobic and anaerobic bacteria and for *Mycoplasma* according to methods previously described.¹²

Quantitation of NAP-1/IL-8. NAP-1/IL-8 was measured with an enzyme-linked immunoassay. The characteristics of this assay have been recently described.13 The sensitivity of the assay in assay buffer is 3 pg/ml, and validation of its use for human amniotic fluid was performed. Fig. 1 illustrates that dilution of the fluid (1:100) was required to achieve parallelism between the standard curve in buffer and in amniotic fluid. The sensitivity of the assay in amniotic fluid was 0.3 ng/ml. The mean intraassay coefficient of variation was determined by assaying 28 replicates of three amniotic fluid samples with detectable NAP-1/IL-8 in the same assay. The mean, standard deviation, and percent coefficient of variation were as follows: For sample 1, mean = 1.6 ng/ml, SD = 0.3 ng/ml, and coefficient of variation = 22%. For sample 2, mean = 50.3 ng/ml, SD = 5.2 ng/ml, and coefficient of variation = 10.3%. For sample 3, mean = 106.4 ng/ml, SD = 9.2 ng/ml, and coefficient of variation = 8.7%. The interassay coefficient of variation was 10.9% (mean of three different assays).

Amniotic fluid absolute neutrophil count. Amniotic fluid white blood cell counts and differential counts were performed in a set of patients with preterm labor and intact membranes. However, this test was performed only rarely in the other study groups. The method used for the amniotic fluid white blood cell count has been recently described.¹⁴

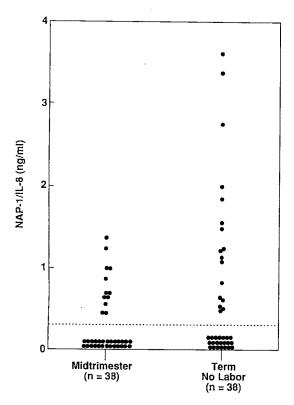

Fig. 2. Amniotic fluid concentrations of NAP-1/IL-8 in women in midtrimester of pregnancy and in women at term not in labor with negative amniotic fluid cultures for microorganisms. Interrupted horizontal line corresponds to sensitivity of assay (0.3 ng/ml). For midtrimester, median = 0 and range = 0to 1.35 ng/ml. For term no labor, median = 0 and range = 0to 3.62 ng/ml. There was no significant difference in median or proportion of women with detectable NAP-1/IL-8 between these two groups. However, proportion of patients with NAP-1/IL-8 concentrations above 1 ng/ml was significantly greater in women at term not in labor (p < 0.01).

Statistical analysis. Comparisons between proportions were performed with either a χ^2 test or Fisher's exact test. A Kruskal-Wallis analysis of variance was used to compare amniotic fluid NAP-1/IL-8 concentrations and absolute neutrophil counts among study groups. Dunn's test was used for multiple post hoc comparisons. A Spearman rank correlation test was used to examine the relationship between the amniotic fluid absolute neutrophil count and amniotic fluid NAP-1/IL-8 concentrations.

Results

Most amniotic fluid samples from women in the midtrimester of pregnancy and at term not in labor did not have detectable immunoreactive NAP-1/IL-8 (Fig. 2). However, the proportion of amniotic fluid samples with NAP-1/IL-8 concentrations above 1 ng/ml was significantly greater in women at term not in labor than in women in the midtrimester of pregnancy (64.7%

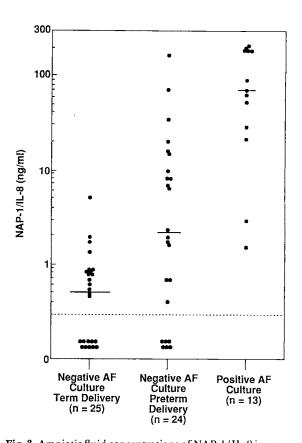

Fig. 3. Amniotic fluid concentrations of NAP-1/IL-8 in women with preterm labor and intact membranes. Interrupted horizontal line corresponds to sensitivity of assay (0.3 ng/ml). For women with negative amniotic fluid cultures and term delivery, median = 0.5 ng/ml and range = 0 to 5.1 ng/ml. For women with negative amniotic fluid cultures and delivery of preterm neonates, median = 2.1 ng/ml and range = 0 to 162 ng/ml. For women with positive amniotic fluid cultures and delivery of preterm neonates, median = 70 ng/ml and range = 1.5 to 203 ng/ml. By Kruskal-Wallis analysis of variance, H = 29.2, p < 0.0001. Patients with positive amniotic fluid cultures had higher median amniotic fluid NAP-1/IL-8 levels than did those in the other two groups (p < 0.05). Patients with negative amniotic fluid cultures and lack of response to tocolysis had significantly higher median NAP-1/IL-8 concentrations than did patients with negative amniotic fluid cultures who responded to tocolysis and had term delivery (p < 0.05).

[11/17] vs 16.6% [2/12]; p < 0.01). All patients in these two groups had negative amniotic fluid cultures for microorganisms.

Fig. 3 illustrates NAP-1/IL-8 concentrations in the amniotic fluid of women with preterm labor and intact membranes. All patients with positive amniotic fluid cultures for microorganisms had detectable amniotic fluid NAP-1/IL-8. Furthermore, these patients had significantly higher amniotic fluid NAP-1/IL-8 levels than did patients with negative amniotic fluid cultures (p < 0.05). Patients with negative amniotic fluid cultures who were unresponsive to tocolysis and had delivery of preterm neonates had significantly higher me-

dian amniotic fluid NAP-1/IL-8 concentrations than did those who responded to tocolysis (p < 0.05).

Table I illustrates the clinical data, microbiologic characteristics, NAP-1/IL-8 concentrations, and placental pathologic features in women with positive amniotic fluid cultures. The most common microbial isolates were *Ureaplasma urealyticum* (n=6) and *Fusobacterium* sp. (n=6). Polymicrobial infections were detected in 30.7% (4/13) of cases, and in 30.7% (4/13) the only isolates were *Mycoplasma*. All patients in whom the placentas were examined had histologic evidence of chorioamnionitis. None of the patients had clinical evidence of chorioamnionitis, and there were no cases of documented neonatal sepsis.

To explore the relationship between amniotic fluid NAP-1/IL-8 immunoreactivity and biologic activity, we examined placental histopathologic characteristics, the amniotic fluid white blood cell count, and amniotic fluid NAP-1/IL-8 levels. Pathologic examination of the placenta was performed in 22 of the 37 patients with preterm delivery. All patients with histologic chorioamnionitis (n=12) had detectable NAP-1/IL-8, whereas 40% (4/10) of those without acute inflammatory lesions of the placenta had detectable amniotic fluid NAP-1/IL-8. The amniotic fluid concentrations of this cytokine were significantly higher in women with histologic chorioamnionitis than in women without acute inflammatory lesions of the placenta (Fig. 4).

Fig. 5 displays amniotic fluid absolute neutrophil counts in patients with preterm labor. It is apparent that the data are similar to amniotic fluid IL-8 concentrations in these patients (Fig. 3). Women with positive amniotic fluid cultures had significantly greater abso-

lute amniotic fluid neutrophil counts than did women with negative amniotic fluid cultures in the other two groups. Although patients who were unresponsive to tocolysis and had negative cultures had higher amniotic fluid neutrophil counts than did women with negative cultures and delivery at term, this difference fell short of reaching conventional significance (p=0.07). There was a significant correlation between amniotic fluid neutrophil count and amniotic fluid NAP-1/IL-8 levels (r=0.44, p<0.001, Spearman rank correlation), but no correlation between cervical dilatation and amniotic fluid NAP-1/IL-8 concentrations (p>0.05, Spearman rank test).

Fig. 6 displays the amniotic fluid NAP-1/IL-8 concentrations of women at term. The amniotic fluid of women in active labor with negative amniotic fluid cultures had significantly higher NAP-1/IL-8 concentrations than did the amniotic fluid of women not in labor. Moreover, in women with positive amniotic fluid cultures concentrations of NAP-1/IL-8 were higher than in women at term in labor. There was no relationship between cervical dilatation and amniotic fluid concentrations of NAP-1/IL-8 (p > 0.05, Spearman rank test).

Table II displays the microbiologic characteristics and amniotic fluid NAP-1/IL-8 levels in women with microbial invasion of the amniotic cavity in term labor. The most common microbial isolate was Ureaplasma urealyticum (n = 11). Polymicrobial infections were detected in 11.1% (2/18) of cases, and in 50% (9/18) the only isolates were Mycoplasma.

Finally, the amniotic fluid of women with preterm labor and positive amniotic fluid cultures had a higher median NAP-1/IL-8 than that of the amniotic fluid of

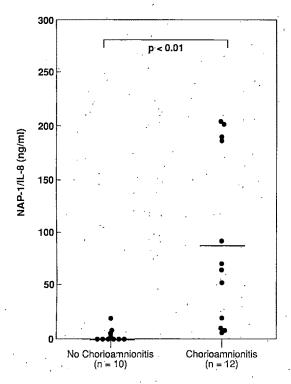

Fig. 4. Amniotic fluid NAP-1/IL-8 concentrations in women with preterm labor and intact membranes who subsequently had delivery of preterm neonates according to placental histopathologic results. In patients with histologic chorioamnionitis amniotic fluid NAP-1/IL-8 values were significantly higher than in women with negative amniotic fluid cultures (for chorioamnionitis, median = 67.8 ng/ml and range = 1.5 to 203 ng/ml; for no chorioamnionitis, median = 0.5 ng/ml and range = 0 to 20.3 ng/ml; p < 0.001, Mann-Whitney U test).

women in labor at term with positive amniotic fluid cultures (for preterm labor, median = 70 ng/ml and range = 1.5 to 203 ng/ml; for term labor, median = 4.8 ng/ml and range = 0.41 to 98.8 ng/ml; p < 0.001, Mann-Whitney *U* test).

Comment

The major finding of this study is that parturition is associated with increased amniotic fluid concentrations of NAP-1/IL-8. This was clearly the case in spontaneous term labor where women with sterile amniotic fluid had a higher median amniotic fluid concentration of NAP-1/IL-8 than did women not in labor at term (Fig. 6). In addition, the median amniotic fluid NAP-1/IL-8 concentration was higher in patients in preterm labor with negative amniotic fluid cultures who progressed to preterm delivery than in patients with preterm labor who responded to tocolysis (Fig. 3). Therefore an elevation in amniotic fluid NAP-1/IL-8 concentrations seems to be a phenomenon associated with labor progressing to delivery. The physiologic role of amniotic fluid NAP-1/IL-8 in parturition has not been determined. Since parturition has been likened

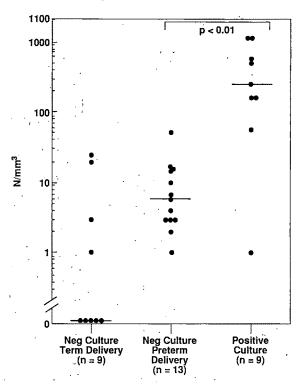

Fig. 5. Neutrophil amniotic fluid count according to amniotic fluid culture results and response to tocolysis of patients with NAP-1/IL-8 determinations in amniotic fluid. Vertical axis displays neutrophils per cubic millimeter. For women with negative amniotic fluid cultures and delivery at term, median = 0 cells/mm³ and range = 0 to 25 cells/mm³. For women with negative amniotic fluid cultures and delivery of preterm neonates, median = 6 cells/mm³ and range = 1 to 50 cells/mm³. For women with positive amniotic fluid cultures and delivery of preterm neonates, median = 260 cells/mm³ and range = 1 to 1100 cells/mm³. By Kruskal-Wallis analysis of variance, H = 15.7; p < 0.0001. Patients with positive amniotic fluid cultures had higher median absolute neutrophil counts than did those in the other two groups (p < 0.01 and p < 0.05). However, difference between absolute amniotic fluid neutrophil counts of patients with negative amniotic fluid cultures and lack of response to tocolysis and those of patients with negative amniotic fluid cultures, response to tocolysis, and delivery at term fell short of reaching significance (p = 0.07).

to an inflammatory process,15 NAP-1/IL-8 may be a signal for neutrophil recruitment and activation in reproductive tissues during labor.

Another major finding of this study is that microbial invasion of the amniotic cavity is associated with an elevation of amniotic fluid NAP-1/IL-8 concentrations. This elevation was dramatic in women with preterm labor and intact membranes (Fig. 3). Since NAP-1/IL-8 is produced by activated macrophages in response to bacterial products⁵⁻⁷ and is an important inflammatory mediator, it is not surprising to find it in such high concentrations in the setting of microbial invasion of the amniotic cavity. The microorganism isolated most frequently from amniotic fluid was Urea-

October 1991 Am J Obstet Gynecol

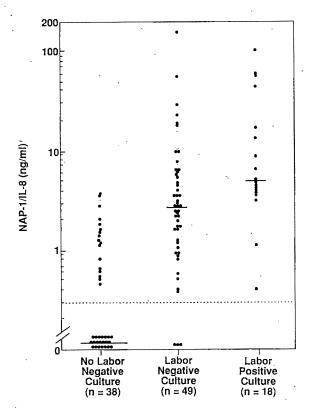

Fig. 6. Amniotic fluid concentrations of NAP-I/IL-8 in women at term. Interrupted horizontal line corresponds to sensitivity of assay (0.3 ng/ml). For women not in labor, median = 0 ng/ml and range = 0 to 3.6 ng/ml. For women in labor with negative amniotic fluid cultures, median = 2.68 ng/ml and range = 0 to 152 ng/ml. For women in labor with positive amniotic fluid cultures, median = 4.8 ng/ml and range = 0.4 to 98.8 ng/ml. By Kruskal-Wallis analysis of variance, H = 47.4; p < 0.0001. Patients with spontaneous labor had higher median amniotic fluid NAP-1/IL-8 concentrations than did women not in labor (p < 0.05). Patients in labor with positive amniotic fluid cultures had higher median amniotic fluid NAP-1/IL-8 concentrations than did women in labor with negative amniotic fluid cultures (p > 0.05 but < 0.10).

plasma urealyticum. This observation is consistent with previous reports from our institution in which this microorganism was the most common isolate from the amniotic fluid of women with preterm premature rupture of membranes or with preterm labor and intact membranes. We have recently demonstrated that women with preterm labor and intact membranes with positive amniotic fluid cultures for *Ureaplasma urealyticum* have a shorter amniocentesis-to-delivery interval than women with sterile amniotic fluid. Moreover, the data presented in this report suggest that microbial invasion of the amniotic cavity with this microorganism is associated with a significant host response as measured by the concentration of NAP-1/IL-8 in the amniotic fluid.

We have no direct evidence for the biologic activity of immunoreactive amniotic fluid NAP-1/IL-8. Such evidence would require purification of NAP-1/IL-8 from amniotic fluid and demonstration of its biologic activity with a bioassay. However, our data indicate a correlation between amniotic fluid concentrations of NAP-1/IL-8 and in vivo indices of inflammation. For example, amniotic fluid NAP-1/IL-8 concentrations were significantly higher in patients with histologic chorioamnionitis than in patients without acute inflammatory lesions of the placenta (Fig. 4). Moreover, there was a correlation between amniotic fluid NAP-1/IL-8 concentrations and amniotic fluid absolute neutrophil count. These data support a role for NAP-1/IL-8 in the recruitment of neutrophils to the maternal-fetal interface and amniotic cavity in the setting of intraamniotic infection. Our results are similar to the observations made by Pankuch et al.16 with the use of an in vitro leukotaxis bioassav.

The magnitude of the increase in amniotic fluid NAP-1/IL-8 concentrations in the setting of microbial invasion of the amniotic cavity was related to gestational age. The median amniotic fluid NAP-1/IL-8 concentration was fourteenfold higher in women with preterm labor and positive amniotic fluid cultures than in women with term labor and positive amniotic fluid cultures. The explanation for this finding is not readily apparent. We explored the possibility that differences in qualitative microbiologic characteristics might be responsible for these observations. However, the proportion of patients with polymicrobial invasion of the amniotic cavity and positive cultures limited to Mycoplasma or with gram-negative microorganisms was not different between the preterm labor and term groups (isolated Mycoplasma: 30.7% [4/13] vs 50% [9/18]; polymicrobial: 30.7% [4/13] vs 11.1% [2/18]; positive cultures with gram-negative microorganisms: 23% [6/13] vs 16.6% [3/18]; all p values >0.05, Fisher's exact test). Although it is possible that the inoculum size might be different between groups, we were unable to test this hypothesis because the majority of patients did not have quantitative microbiologic evaluation. An alternative view is that the concentration of NAP-1/IL-8 in amniotic fluid is dependent on the pathway of microbial invasion and the time allowed for microbe-host interaction before amniocentesis. Amniotic fluid NAP-1/IL-8 is thought to be, at least partially, of decidual origin (Romero R. Unpublished observations), and therefore the state and duration of decidual activation may be critical to the secretion of NAP-1/IL-8 into the amniotic fluid. If microorganisms from the lower genital tract gain access to the amniotic cavity directly without a significant "decidual stage," NAP-1/IL-8 secretion into the amniotic fluid could be modest or even absent. This may be the course of events in term labor with microbial invasion of the amniotic cavity. On the other hand, if microorganisms gain ac-

cess to the decidua for a sufficient time, NAP-1/IL-8 secretion by activated macrophages may lead to significant accumulation of this cytokine in the amniotic cavity. We propose that this is the likely course of events in premature labor with intact membranes.

The demonstration of the presence of NAP-1/IL-8 in the amniotic cavity is of considerable biologic importance because this peptide is an inflammatory mediator and enhances host defense against infection. In the uterus the first cellular line of defense against infection is probably resident decidual macrophages. Activation of these cells by microbial products leads to NAP-1/IL-8 production (Romero R. Unpublished observations), which, in turn, may recruit neutrophils to the site of microbial invasion. Interleukin-1 and tumor necrosis factor are also produced by human decidua in response to bacterial products,17.18 and these two cytokines can induce IL-8 production by several cell types. 19-24 Thus decidua contains the cellular elements necessary for the existence of an amplification loop to ensure adequate recruitment and activation of neutrophils for host defense. During the course of parturition, tissue disruption and noninfectious inflammatory mediators may lead to secretion and recruitment of neutrophils. In this setting neutrophils may play an important role in clearing cellular debris after delivery of the placenta, thereby enabling normal uterine involution.

In conclusion, we have demonstrated NAP-1/IL-8 is part of the host response to microbial invasion of the amniotic cavity and that amniotic fluid concentrations of this cytokine increase during preterm and term parturition. Further studies are required to establish the sources, regulatory mechanism, and biologic functions of this cytokine in reproductive tissue. Studies are also required to determine the relative role of NAP-1/IL-8 in the intrauterine cytokine network.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of \$61.00 for domestic, \$88.27 for Canada, and \$84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. Payment must accompany all orders. Contact Mosby—Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

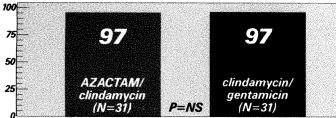

IN POSTPARTUM ENDOMETRITIS*

A ZACTAM d&livers more than you're & Specting...

- Broad aerobic gram-negative in vitro coverage, including <u>Escherichia coli</u>, <u>Proteus mirabilis</u>, and Enterobacter cloacae.
- Greater than 90% cure rates in combination with clindamycin.¹⁻³
- No time-consuming, costly, routine therapeutic drug monitoring.
- May be used in penicillin-allergic patients.[‡]
- Pregnancy Category B.

There are no adequate and well-controlled studies in pregnant women. AZACTAM should be used in pregnant women only if clearly needed.

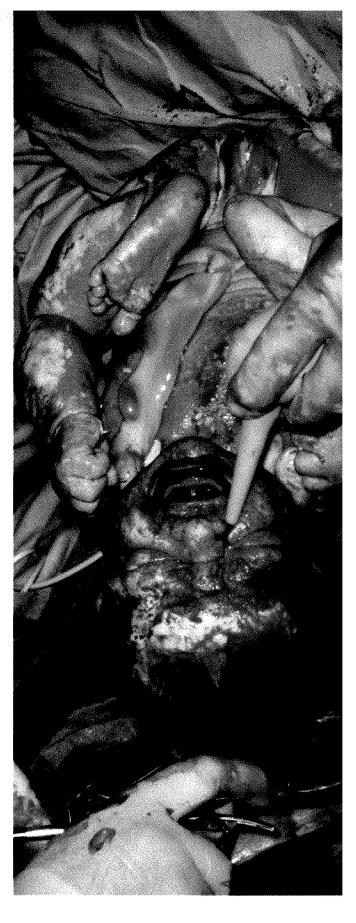

A randomized, comparative trial of AZACTAM versus gentamicin, each with clindamycin, for the treatment of endometritis after delivery.

No universal criteria exist that may satisfy a single definition of "cure." Use of this term may vary between clinical settings and investigators, and the reader is urged to consult the references listed.

Azactam® aztreonam IV/IM 1g/2g

A logical alternative to aminoglycosides.

*Due to susceptible organisms.

*Although a useful guide, in vitro data do not necessarily correlate with therapeutic outcome.

*Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. See full prescribing information for recommendations on patients with immediate hypersensitivity reactions to penicillins.

Following IV administration, the most commonly seen adverse reactions occurred in less than 2% of patients, including local reactions, diarrhea, nausea/vomiting, and rash

Please see adjacent page for brief summary of prescribing information.

Azactam[®] aztreonam IV/IM 1g/2g

AZACTAM* FOR INJECTION Aztreonam For Injection

DESCRIPTION-AZACTAM (Aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a totally synthetic bactericidal antibiotic with activity against a wide spectrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different from other beta-lactam antibiotics.

AZACTAM For Injection is a sterile, nonpyrogenic, sodium-free, white to yellowishwhite lyophilized cake, containing approximately 780 mg arginine per gram of aztreonam for intramuscular or intravenous use following constitution. Aqueous solutions of the product have a pH in the range of 4.5-7.5.

INDICATIONS AND USAGE—Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causative organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of the susceptibility testing are available; subsequently, appropriate antibiotic therapy should be continued.

AZACTAM For Injection is indicated for the treatment of the following infections caused by susceptible gram-negative microorganisms: Urinary Tract Infections (conplicated), including pyelonephritis and cystitis (initial and recurrent) caused by Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella oxytoca*, Citrobacter species* and Serratia marcescens*. Lower Respiratory Tract Infections, including pneumonia and bronchitis caused by Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae, Proteus mirabilis, Enterobacter species and Serratia marcescens*. Septicemia caused by Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus mirabilis*, Serratia marcescens* and Enterobacter species Skin and Skin-Structure Infections, including those associated with postoperative wounds, ulcers and burns caused by Escherichia coli, Proteus mirabilis, Serratia marcescens, Enterobacter species*, Pseudomonas aeruginosa, Klebsiella pneumoniae, and Citrobacter species* intra-abdominal Infections, including peritonitis caused by Escherichia coli, Klebsiella species, including K. pneumoniae, Enterobacter species* including E. cloacae*, Pseudomonas aeruginosa, Citrobacter species* including C. freundii* and Serratia species* including S. marcescens*. Gynecologic Infections, including endometritis and pelvic cellulitis caused by Escherichia coli, Klebsiella pneumoniae*, Enterobacter species* including E. cloacae* and Proteus mirabilis*.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is effective against most of the commonly encountered gramnegative aerobic pathogens seen in general surgery.

Concurrent Therapy—Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organism(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an anti-anaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase *in vitro* in some gram-negative aerobes such as *Enterobacter* and *Pseudomonas* species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These *in vitro* findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATIONS—Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS—Pseudomembranous colitis has been reported with nearly all antibacterial agents, including aztreonam, and may range in severity from mild to lifethreatening. Therefore, it is important to consider this diagnosis in patients who present with diarrhea subsequent to the administration of antibacterial agents.

Treatment with antibacterial agents alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by *Clostridium difficile* is one primary cause of "antibiotic-associated colitis."

After the diagnosis of pseudomembranous colitis has been established, therapeutic measures should be initiated. Mild cases of pseudomembranous colitis usually respond to drug discontinuation alone. In moderate to severe cases, consideration should be given to management with fluids and electrolytes, protein supplementation, and treatment with an oral antibacterial drug effective against *C. difficile* (e.g., vancomycin).

*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

PRECAUTIONS—General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed in vivo and in vitro with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy-Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers—Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use-Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS—Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity: Hypersensitivity—anaphylaxis, angioedema, bronchospasm. Hematologic—pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. Gastrointestinal—abdominal cramps; rare cases of C. difficile-associated diarrhea, including pseudomembranous colitis, or gastrointestinal bleeding have been reported. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment (see WARNINGS). Dermatologic—purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. Cardiovascular—hypotension, transient ECG changes (ventricular bigeminy and PVC). Respiratory—one patient experienced flushing, chest pain, and dyspnea. Hepatobiliary—hepatitis, jaundice. Nervous System—seizure, confusion, vertigo, paresthesia, insomnia, dizziness. Musculoskeletal—muscular aches. Special Senses—tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. Other—vaginal candidiasis, vaginitis, breast tenderness. Body as a Whole—weakness, headache, fever, malaise.

Adverse Laboratory Changes—Those reported without regard to drug relationship during clinical trials were: *Hepatic*—elevations of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). *Hemic*—increases in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. *Henal*—increases in serum creatinine.

OVERDOSAGE—If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION-Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED–AZACTAM For Injection (Aztreonam For Injection)–Lyophilized–is supplied in single-dose 15 mL vials containing **500 mg**, or **1 g**/vial; in single-dose 30 mL vials containing **2 g**/vial; and in single-dose 100 mL intravenous infusion bottles containing **500 mg** or **1 g** or **2 g**/bottle.

Consult package insert before prescribing AZACTAM (aztreonam). (J4-231E)

TRI-LEVLEN® Levonorgestrel and ethinyl estradiol tablets-Triphasic regimen

TRI-LEVLEN® 28 TRI-LEVLEN® 21

BRIEF SUMMARY

BRIEF SUMMARYTri-Levien®—6 brown toblets, each containing 0.050 mg of levonorgestrel (d.-)-13 beta-ethyl-17-olpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17a-pregna-1.3.5(10)-trien-20-yne-3, 17-diol), 5 white toblets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol, 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use this product as a method of contraception

Controlidections:

Croil confragetives should not be used in women with any of the following conditions: thrombophiebitis or thromboembolic disorders, a past history of deep-vein thrombophiebitis or thromboembolic disorders, cerebral-vascular or coronary-artery disease, known or suspected carcinoma of the breast, carcinoma of the endometrium or other known or suspected estragendependent peoplosia, undiagnosed abnormal genital bleeding, cholestatic jaundice of pregnancy or jaundice with prior pitiuse, hepatic adenomas ar carcinomas, known or suspected pregnancy.

Marnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

who use and contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocordial infarction, thromboemboism, stroke, hepatic neoplosis, galibloader disease, and hyperfension, although the risk of serious morbidly or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and morbidity increases significantly in the presence of other underlying risk factors such as hyperfension, hyperipidemias, obesity and diabetes. Practition-ers prescribing and contraceptives should be familiar with the following information relating to these risk in incommon error process. The information contained in this package insert is principally based on studies carried out in patients who used and contraceptives with higher formulations of stripages and progestogens from the roleowing information relating to these risks of relating the contraceptive with lower formulations of both estragens and progestogens remains to be determined. Throughout this labeling, epidemiological studies reported are of two types, retrospective or case control studies and prospective or cord contraceptive users to that among nanusers. The relative risk of disease, namely, a ratio of the incidence of a disease among arabicontraceptive users and nanusers. The relative risk of disease, namely, a ratio of the incidence of a disease among arabicontraceptive users and nanusers. The entitubule risk does provide information about the actual ccinical occurrence of a disease. Contrative price and contraceptive users and nanusers. The entitubule risk does provide information about the actual ccinical occurrence of a disease. Although a propulation. For further information, the redder is referred to a text on epidemiological methods.

Intromboembolic Disorders and Other Vascular Problems

A Myocordial Infactant. An increased risk of myocordial infaction has been attributed to oral-contraceptive user. The risk is surpriorly in

- risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thramboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to nonusers to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep-vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to ard contraceptives and related to length of use and disappears after pill use is stopped. A two-of todi increase in relative risk of postoperative thromboembolic complications has been reported with the use of and contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such moment who have predisposing conditions is wice that of women without such model conditions. If feasible, and contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate post partum period is also associated with an increased risk of thromboembolism, and contraceptives should be started no earlier than four to six weeks after delivery in women who elect not to breast-feed, or a midtrimester pregnancy termination. pregnancy termination.
- pregnancy termination.

 c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of serebrovascular diseases. Oral contraceptives disease, and to be a risk factor for both users and nonusers for both types of strokes, while smoking interacted to increase the risk for hemorrhagic strokes in a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The attributable risk is also greater in older women.

 A Dose-related risk of vascular disease from roal contraceptives. 18 for normotensive users on 25.7 for users with severe hypertension. The attributable risk is also greater in older women.

 A Dose-related risk of vascular disease from roal contraceptives. A positive association has been observed between the amount of estragen and progestagen in and contraceptives and the risk of vascular disease. A decline in serum high-density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high-density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high-density lipoproteins (HDL) has been associated with an increased incidence of ischemic heard disease. Because estrogens and progestagen and the nature and absolute amount of progestagen are in the contraceptive. The amount of both hormones should be considered in the contraceptive. The amount of both hormones should be considered in the contraceptive amount of progestagen and the needs of the individual potent. New acceptors of oral-contraceptive agents should be storted on preparations containing less than 50 mcg of estragen.
- of estrogen.

 e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of and contraceptives. In a study in the United States, the risk of developing myocardial inforction after discontinuing, and contraceptives persists for all easily syears for women 40-49 years who had used and contraceptives for more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted of at least 6 years after discontinuation of and contraceptives, although excess risk was very small. However, both studies were performed with analysis of estrogens.
- cell estinguies.

 2. Estimates of Mortality from Contraceptive Use. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method folium. Each method of contraceptive methods plus the risk attributable to pregnancy in the event of method risk of death associated with contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth contral is less than that associated with childrinh. The observation of a possible increase in risk of mortality with age for oraccontraceptive users is based on data gathered in the 1970 s-but not reported until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of orac-contraceptive use to women who do not have the various risk factors listed in this labeling. Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Moternal Health Turgs Advisory Committee was asked to review the topic in 1989. The Committee concluded that dithough cardiovascular disease with the use of oral contraceptive use enter age 40 in healthy nonsmoking women (even with the newer low-dose formulations), there are switch may be necessary if such women and on that over access to effective and acceptable means of contraceptive. Therefore, thick may be necessary if such women and on that over access to effective and acceptable means of contraception. Therefore the Committee recommended that the benefits of orai-contraceptive use by healthy nonsmoking women over 40 may autweigh the possible risks. Of course, older women, as all women who take oral contraceptives,
- is effective.

 3. Carpinana of the Reproductive Organs. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarion and servical cancer in women using and contraceptives. The overwhelming evidence in the literature suggests that use of and contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone (CASH) states of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone (CASH) states are sufficiently also showed no latent effect on the risk of developing press cancer, of though the methodology of the studies have shown a slightly increased relative risk of developing presst cancer, of though the methodology of the studies. Surjective studies suggest that and-contraceptive use has been associated with an increase in the risk of cervical intrapethietial nepilical or some populations of women. However, there continues to be controvery about the extent to which such findings may be due to differences in sexual behavior and other factors. In spite of many studies of the relationship between ori-contraceptive use and breast and cervical cancers, a cause-and-effect relationship has not been established.

 A Hepatic Nepolosia. Bening hepatic adenomas are associated with ori-contraceptive use and the residence of bening the part of the relationship to the contracent of the relationship the part of the relationship to the contracent of the relationship to the relati
- 4. Hepatic Neoplasia. Benign hepatic adenomas are associated with oral-contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use, Rupture of rare, benign, hepatic across any acuse death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular.

carcinoma in long-term (>8 years) oral-contraceptive users. However, these cancers are extremely rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral-contraceptive users approaches less than one per million users. 5. Ocular Lesions. There have been clinical case reports of retinal thrombosis associated with the use of oral controceptive Soral controceptives of the control through the con

- token immediately.

 6. Onto-Contraceptive Use Before or During Early Pregnancy Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used and contraceptives prior to pregnancy. Studies also do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb-reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives in induce withdrawal bleeding should not be used so test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any potient who has missed from consecutive periods, pregnancy should be considered that for any potient who has missed from consecutive periods, pregnancy should be considered at the time of the first missed period. Oral-contraceptive use should be discontinued if pregnancy is continued.

 7. Gallbladder Disease Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral-contraceptive uses may be minimal. The recent findings of minimal tisk may be related to the use of oral-contraceptive formulations containing lower hormonal doses of estrogens and progestogens.
- Infinition Continuing Jower normal abuses of earningers and projectogens.

 8. Carbohydrate and Lipid Metabolic Effects, Ordi controceptives have been shown to cause glucose intolerance in a significant percentage of users. Ordi controceptives containing greater than 75 micrograms of estragens cause hyperinsulinism, while lower doses of estragen cause less glucose intolerance. Progestagens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the nondiabetic women, and controceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while foking and controceptives. A small proportion of women with laves persistent hypertriplycenia while on the pill. As discussed earlier (see: "Womings" to and Id.), changes in serum triglycerides and lipoprotein levels have been reported in ordi-controceptive. As million of controceptive and the programment of the pill. n oral-contraceptive users.
- in oral-contraceptive users.

 9 Elevated Blood Pressure An increase in blood pressure has been reported in women taking and contraceptives and this increase is more likely in older oral-contraceptive users and with continued use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hyperfersions increases with increasing quantiles of progestogers. Women with a history of hyperfension or higher decisions, and increases in the increasing quantiles of contraception. If women with hyperfension elect to use and contraceptives, they should be encouraged to use another method of contraception. If women with hyperfension elect to use and contraceptives, they should be monitored closely, and if significant leviation of blood pressure occurs, and contraceptives should be disconfinued from solventing, elevated blood pressure will return to normal after stopping and contraceptives, and there is no difference in the occurrence of hyperfension among ever-and never-users. of hypertension among ever-and never-users.

of hypertension among ever-and never-users.

O Headache The onset or exocerbation of migraine or development of headache with a new pattern that is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

Il Bleeding Irregularities Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. The type and dose of progestagen may be important. Nonhormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal regional bleeding; if pothology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pall amenorrhea or oligomenorrhea, especially when such a condition was preexistent.

post-pill amenormeo or oligomenormea, especially when such a condition was pressistent.

Procourtions

1. PHYSICAL EXAMINATION AND FOLLOW UP A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure breads, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted for uite out malignancy. Women with a strong farmily history of breads concer or who have breast nodules should be manifored with particular care 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be monitored with particular care 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be monitored with particular care 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias the control of hyperlipidemias more difficult (See "Wornings" to). J. LIVER PUNCTION. If jounded develops in any woman receiving such drugs, the medication should be discontinued. Steriot hormones may be poorly meribobilized in prients with imported fiver function. A FUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with coultion, and only with careful monitoring, in potients with conditions which might be aggravated by fluid retention. S. BMOTIONAL DISORDERS, Polientes becoming significantly depressed while toxing prot contraceptives should stop the medication and use an attempte method of contraceptive in an attempt to determine whether the symptom is drug related. Women with a history of depression should be carefully observed and the drug discontinued

Information for the Patient See Patient Labeling.

Adverse Reactions

Adverse Reactions An increased risk of the following serious adverse reactions has been associated with the use of and contraceptives (see "Warnings' section): thrombophilebits, orteriol thromboembolism, pulmonary embolism, myocardial infarction, cerebral hemorrhage, cerebral thrombosis, hypertension, galibladder disease, hepatic adenomas or benign liver tumors. There is evidence of an association between the following conditions and the use of anal contraceptives, although additional confirmatory studies are needed: mesenteric thrombosis, retinal thrombosis.

The following adverse reactions have been reported in patients receiving and contraceptives and are believed to be drug related nouses, worning adverse reactions have been reported in patients receiving and contraceptives and are believed to be drug related nouses, worning, gastromitestinal symptoms (such as obdominal cramps and bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorable, temporary interfillity after discontinuation of treatment; edema, melasorable may presist, breast changes: tenderness, enlargement, secretion, change in weight (increase or decrease), change in cervical erosion and secretion, diminution in lactation when given immediately postpartum; cholestatic joundice; migraine; rask (allergic), mental depression, reduced folerance to carbohydrates, vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

tool lenses.

lowing adverse reachions have been reported in users of oral contraceptives and the association has been neither confirmed
uted: congenital anomalies, premenstrual syndrome, cataracts, optic neuritis, changes in appetite, cystitis-like syndrome,
chernousness, dizziness, hirsultism, loss of scolp had, eighterna multiforme, cerebral-vascular disease with mitral valve
se, lupus-like syndromes, enthema nodosum, hemormogic eruption, vagaintis, porphyria, impaired renal function, hemolytic
syndrome, Budd-Chlori syndrome, acne, changes in libido, colifis, sickle-cell disease.

Overdosage
Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children.
Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Overloosage may evous housed, and winnorwal obesing may occur in temales.

The following nancontraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which tangely utilized oral-contraceptive formulations containing doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestronol.

Effects on menses: increased menstrual cycle regularity, decreased blood loss and decreased incidence of iron-deficiency onemia, decreased incidence of dysmenorthea.

Effects related to inhibition of ovulation: decreased incidence of functional ovarian cysts, decreased incidence of ectopic pregnancies.

Effects from long-term use: decreased incidence of fibroadenomas and fibrocystic disease of the breast, decreased incidence

of acute pelvic inflammatory disease, decreased incidence of endometrial cancer, decreased incidence of ovarian cancer Dosage and Administration
To achieve maximum continues

Debugge and Administration

To achieve maximum contraceptive effectiveness, TRI-LEVLEN® tablets (Levonorgestrel and Ethinyl Estradiol Toblets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours.

For full details on dosage and administration see prescribing information in package insert.

Amniotic fluid white blood cell count: A rapid and simple test to diagnose microbial invasion of the amniotic cavity and predict preterm delivery

Roberto Romero, MD, Ruben Quintero, MD, Jose Nores, MD, Cecilia Avila, MD, Moshe Mazor, MD, Shuichi Hanaoka, MD, Zion Hagay, MD, Lydia Merchant, MS, and John C. Hobbins, MD

New Haven, Connecticut

The purpose of this study was to determine the value of amniotic fluid white blood cell count in the diagnosis of microbial invasion of the amniotic cavity. Amniotic fluid was retrieved by amniocentesis from 195 patients with preterm labor and intact membranes. Fluid was cultured for aerobic and anaerobic bacteria, as well as for mycoplasmas. The prevalence of a positive amniotic fluid culture was 12.8% (25/195). Patients with a positive amniotic fluid culture had a significantly higher median amniotic fluid white blood cell count than did patients with a negative amniotic fluid culture (median, 6 cells/mm3; range, 0 to 11,000 cells/mm³ vs median, 320 cells/mm³; range, 1 to 4480 cells/mm³; ρ < 0.0001). An amniotic fluid white blood cell count ≥50 cells/mm³ had a sensitivity of 80% (20/25), a specificity of 87.64% (149/170), a positive predictive value of 48.78% (20/41), and a negative predictive value of 96.75% (149/154) in the detection of a positive amniotic fluid culture for microorganisms. Although the sensitivity of an amniotic fluid white blood cell count (≥50 cells/mm³) in the detection of microbial invasion of the amniotic cavity was greater than that of the Gram stain of amniotic fluid (80% [20/25] vs 48% [12/25]; p < 0.05), the specificity was lower (87.64% [149/170] vs 98.8% [168/170]; p < 0.05). However, 88% (15/17) of all patients with an amniotic fluid white blood cell count ≥50 cells/mm³ and a negative amniotic fluid culture had a spontaneous preterm delivery. We conclude that the amniotic fluid white blood cell count is a sensitive, simple, and inexpensive test for the detection of microbial invasion of the amniotic cavity. An elevated amniotic fluid white blood cell count is a risk factor for preterm delivery. (AM J OBSTET GYNECOL 1991;165:821-30.)

Key words: Neutrophils, leukocytes, amniotic fluid, preterm labor, prematurity, chorioamnionitis, tocolysis, labor, Gram stain, Mycoplasma, Ureaplasma urealyticum

The rapid and accurate diagnosis of microbial invasion of the amniotic cavity remains an important clinical challenge. Patients with preterm labor and intact membranes with a positive amniotic fluid culture for microorganisms are more likely to have preterm delivery¹⁻⁷ and are at increased risk for both maternal (reviewed in reference 8) and neonatal infection-associated morbidity as compared with patients with a negative amniotic fluid culture.⁸⁻¹⁰

In centers using amniocentesis in the management of preterm labor, the Gram stain is used for the rapid detection of microbial invasion of the amniotic

From the Departments of Obstetrics and Gynecology and Laboratory Medicine, Yale University School of Medicine.

Presented at the Eleventh Annual Meeting of the Society of Perinatal Obstetricians, San Francisco, California, January 28—February 2, 1991

Reprint requests: Roberto Romero, MD, Department of Obstetrics and Gynecology, 333 Cedar St., PO Box 3333, New Haven, CT 06510. 6/6/31200 cavity.¹⁻¹⁰ However, the Gram stain detects microorganisms in only 50% of cases with a positive amniotic fluid culture.¹¹ Neonatal infection-related morbidity remains high in patients with a false-negative Gram stain¹¹; therefore the search for other methods to identify microbial invasion of the amniotic cavity is justified.

The white blood cell count has been used for the diagnosis of infection in other body fluids such as cerebrospinal fluid, ¹² synovial fluid, ¹³ and pleural fluid. ¹⁴ Previous reports examining the value of white blood cells in amniotic fluid in the diagnosis of microbial invasion of the amniotic cavity have yielded conflicting results. ^{1, 15-19} The purpose of this study was to determine the role of the amniotic fluid white blood cell count in the diagnosis of a positive amniotic fluid culture for microorganisms.

Material and methods

Patient population. One hundred ninety-five consecutive patients admitted to Yale—New Haven Hospital over a 31-month period with the diagnosis of preterm labor and singleton gestation underwent amniocentesis

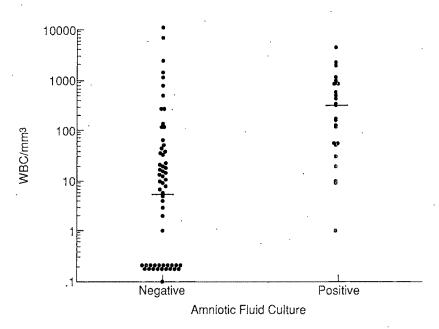

Fig. 1. Amniotic fluid white blood cell counts (WBC/mm³) in patients in preterm labor with intact membranes. Patients with a positive amniotic fluid culture had significantly higher median amniotic fluid white blood cell count than did patients with a negative amniotic fluid culture (median, 320 cells/mm³; range, 1 to 4480 cells/mm³ vs median, 6 cells/mm³; range, 0-11,000 cells/mm³; $\rho = 0.0000001$, Mann-Whitney U test).

for the assessment of the microbiologic status of the amniotic cavity. Preterm labor was defined as the presence of regular uterine contractions with a frequency of at least two every 10 minutes. Rupture of membranes was excluded by testing for pooling, Nitrazine paper reaction, and ferning. Patients were hydrated for I hour with at least 1 L of lactated Ringer's solution, and if contractions persisted, the patient was started on a regimen of intravenous tocolysis with ritodrine, terbutaline, or magnesium sulfate. The protocol for tocolysis with β-adrenergic agents followed the guidelines proposed by Caritis.20 Magnesium sulfate was given as a loading dose of 4 gm, followed by a rate of 2 mg/hr, which was increased to 3 to 4 gm/hr if needed. Failure of tocolysis was defined as progressive cervical dilatation beyond 5 cm or delivery of the infant.

Retrieval of amniotic fluid. Amniotic fluid was retrieved by transabdominal amniocentesis, which was performed under antiseptic conditions, with a 22-gauge needle monitored with ultrasound.

Microbiologic culture technique. Amniotic fluid was transported to the laboratory in a capped plastic syringe. Plating occurred within 30 minutes of collection. Amniotic fluid was cultured for aerobic and anaerobic bacteria, as well as for mycoplasmas, according to methods previously described.²¹

Gram stain examination. Gram stain examination was performed with commercial reagents (crystal violet, saffranin, and Gram's iodine, Difco Laboratories, Detroit) under standard conditions. Stained slides were

examined by trained technologists, and the presence or absence of microorganisms was noted. The results of the Gram stain examinations were communicated to the clinicians. Patients with a negative Gram stain examination underwent tocolysis. Patients with a positive Gram stain examination of amniotic fluid for bacteria were given parenteral antibiotics and were delivered. A positive Gram stain for bacteria was an indication for discontinuing tocolysis.

Amniotic fluid white blood cell count. An aliquot of amniotic fluid was transported to the hematology laboratory and examined under a hemocytometer (Neubauer ruled) for the presence of white blood cells. The absolute white blood cell count was calculated by multiplying the area examined by a factor of 10 per area and expressed as number of cells per cubic millimeter.

Amniotic fluid white blood cell differential count. An aliquot of amniotic fluid was placed in a cytocentrifuge chamber (Cytospin 2, Shandon Scientific, London). The specimen was centrifuged for 10 minutes at 117g, allowed to air-dry, and stained with Wright's stain. The amniotic fluid white blood cell differential was calculated after 100 cells were counted. If the specimen had <100 cells, then 10, 25, or 50 cells were counted, and the differential count was calculated accordingly. The results of either the amniotic fluid white blood cell count or the differential count were not made available to the clinicians.

Criteria for the diagnosis of chorioamnionitis and neonatal sepsis. Microbial invasion of the amniotic cav-

ity was defined as the presence of a positive amniotic. fluid culture.* Clinical chorioamnionitis was defined according to the criteria proposed by Gibbs.22 Neonatal sepsis was diagnosed by the presence of a positive culture of blood, urine, or cerebrospinal fluid.

Statistical analysis. A Mann-Whitney test was used to compare the amniotic fluid white blood cell count in patients with a positive or negative amniotic fluid culture. Receiver-operator characteristic curve analysis was performed with the True Epistat software package (Epistat Services, Richardson, Tex.). Diagnostic indices (sensitivity, specificity, positive predictive value, and negative predictive value) were calculated for the Gram stain and different cutoff levels of amniotic fluid white blood cell count in the diagnosis of infection. Similarly, diagnostic indices were calculated for different levels of amniotic fluid white blood cell count in the prediction of response to tocolysis. Comparisons between sensitivity and specificity of the Gram stain and amniotic fluid white blood cell counts were performed with a modified t test for correlated samples, as described by Galen and Gambino.23

Results

One hundred ninety-five patients were included in the study; 43% (84/195) had delivered at term. The prevalence of a positive amniotic fluid culture was 12.8% (25/195). Table I describes the clinical characteristics of patients with positive and negative amniotic fluid cultures. Patients with a positive amniotic fluid culture had a significantly lower gestational age and a more advanced cervical dilatation than did patients with a negative amniotic fluid culture. Fig. 1 displays the amniotic fluid white blood cell count according to culture results. Patients with a positive amniotic fluid culture had a significantly higher median amniotic fluid white blood cell count than did patients with a negative amniotic fluid culture (median, 6 cells/mm³; range, 0 to 11,000 cells/mm3 vs median, 320 cells/mm3; range, 1 to 4480 cells/mm³; p < 0.0000001, Mann-Whitney U test).

To describe the relationship between the sensitivity

(true-positive rate) and the false-positive rate (1 – specificity) of amniotic fluid white blood cell count in the detection of a positive amniotic fluid culture, a receiver-operator characteristic curve was constructed. Fig. 2 shows this receiver-operator characteristic curve (area under the curve, 0.823; SE, 0.04; z = 8.110; p < 0.0000001). The curve lies significantly above the 45-degree line, suggesting that a higher amniotic fluid white blood cell count increases the probability of a positive amniotic fluid culture. As with any other diagnostic test, there is a trade-off between the sensitivity and the false-positive rate (1 - specificity).

Table II displays the median percent amniotic fluid white blood cell differential count according to culture results. The median percent of neutrophils and macrophages was significantly higher in patients with a positive amniotic fluid culture than in patients with a negative amniotic fluid culture. Patients with a positive amniotic fluid culture had a significantly higher median absolute amniotic fluid neutrophil count than did patients with a negative amniotic fluid culture (median, 175 cells/mm³; range, 0 to 3853 cells/mm³ vs median, 4 cells/mm³; range, 0 to 10,120 cells/mm³; p = 0.0001, Mann-Whitney U test). Fig. 3 displays the comparison between the receiver-operator characteristic curve of the amniotic fluid white blood cell count and that of the amniotic fluid absolute neutrophil count in the diagnosis of a positive amniotic fluid culture (area under the curve, 0.771; SE, 0.004; z = 6.68; p < 0.05). In the diagnosis of microbial invasion of the amniotic cavity the performance of the amniotic fluid absolute neutrophil count was similar to that of the total amniotic fluid white blood cell count. No difference between the two curves was detected (p = 0.34).

There was no difference in the absolute red bloodcell count between patients with a positive and a negative amniotic fluid culture (median, 168 cells/mm³; range, 8 to 98,000 cells/mm³ vs median, 53; range, 0 to 116,000 cells/mm³, respectively; p > 0.05). There was a correlation between amniotic fluid white blood cell and red blood cell count (r = 0.45, p < 0.05; Spearman's correlation coefficient). However, this correlation

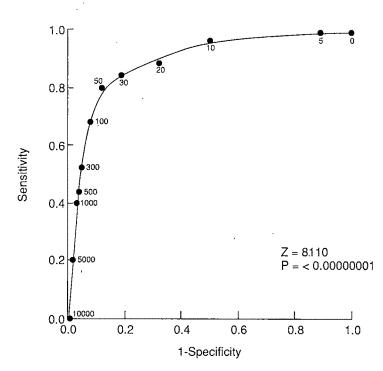

Fig. 2. Receiver-operator characteristic curve analysis of amniotic fluid white blood cell counts in the diagnosis of a positive amniotic fluid culture. *Numbers* next to *solid dots* represent amniotic fluid white blood cell counts (cells per cubic millimeter) (area under curve, 0.823; SE, 0.04; z = 8.110; p < 0.0000001).

Table II. Comparison of amniotic fluid white blood cell differential count between patients with positive and negative amniotic fluid cultures

	Positive culture		Negative	culture	
	Median (%)	Range (%)	Median (%)	Range (%)	p Value

Amniotic fluid white blood cell differential count is expressed as percentage of total white blood cells. NS, Not significant.

is not significant when the analysis is restricted to patients with a positive amniotic fluid culture (r = 0.37, p = 0.07).

Table III displays the diagnostic indices of the Gram stain and the amniotic fluid white blood cell count with different cutoff levels. An amniotic fluid white blood cell count of ≥ 50 cells/mm³ had a greater sensitivity than the Gram stain of amniotic fluid in the detection of a positive culture (80% [20/25] vs 48% [12/25]; p < 0.05).

When the Gram stain and amniotic fluid white blood cell count were used in combination (a positive Gram stain or an amniotic fluid white blood cell count ≥50 cells/mm³ considered abnormal), the diagnostic indices were as follows: sensitivity, 84% (21/25); specificity,

88.82% (151/170); positive predictive value, 52.50% (21/40); negative predictive value, 97.41% (151/155).

One hundred seventy-eight patients had a negative Gram stain and an amniotic fluid white blood cell count of <50 cells/mm³. Four of these patients had a positive amniotic fluid culture (two with *Ureaplasma urealyticum*, one with mixed anaerobic flora, and one with *Candida albicans*). Tocolysis failed in all four patients and all had premature delivery.

Table IV displays the clinical data of the 17 patients with an amniotic fluid white blood cell count ≥50 cells/mm³ and a negative amniotic fluid culture. Eighty-eight percent (15/17) of these patients had refractory preterm labor that led to preterm delivery. Seventy-six percent (10/13) of patients showed histologic evidence

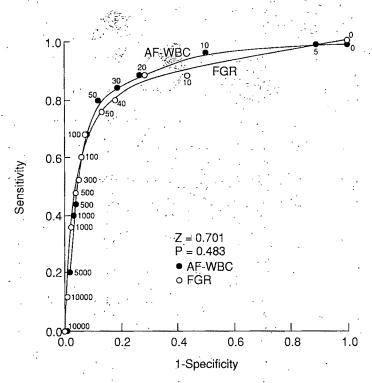

Fig. 3. Comparison of receiver-operator characteristic curve analysis of amniotic fluid white blood cell count (AF-WBC) and absolute granulocyte count (FGR) in the diagnosis of a positive amniotic fluid culture. Numbers next to solid dots represent amniotic fluid white blood cell counts (cells per cubic millimeter) and those next to clear dots represent absolute granulocyte counts (neutrophils per cubic millimeter). No significant difference between these two curves was found.

of chorioamnionitis. One patient was delivered by cesarean section at 35 weeks because of suspected abruptio placentae, which was not confirmed at placental examination. Two patients carried their pregnancies to term; one of them had a total amniotic fluid white blood cell count of 133 cells/mm³ and 116 neutrophils/mm³, and the other had a total amniotic fluid white blood cell count of 130 cells/mm³ and 98 neutrophils/mm³.

Table V displays the clinical course and microbiologic findings of patients with a positive amniotic fluid culture. Twenty-eight percent of patients had polymicrobial infections. Thirteen patients had a negative Gram stain for microorganisms, and nine of these patients had an amniotic fluid white blood cell count >50 cells/mm3.

Clinical chorioamnionitis occurred in 2% (4/195) of patients. Only one patient had a positive amniotic fluid culture (Escherichia coli); the Gram stain of amniotic fluid showed gram-negative rods, and the amniotic fluid white blood cell count was 52 cells/mm3. The placenta showed histologic evidence of chorioamnionitis. The amniotic fluid white blood cell counts of the other patients were 23, 16, and 2 cells/mm3. Only one placenta from these three patients was examined, and no acute inflammatory lesions were found.

No neonate had a positive blood, urine, or cerebrospinal fluid culture. However, two neonates were diagnosed as having presumed sepsis. One was born to a mother who had a positive amniotic fluid culture (Enterococcus) at an outside hospital with a colony count of >10⁵ colony forming units per milliliter and had been treated with ampicillin for a possible urinary tract infection before transfer to our institution. The amniotic fluid culture from repeat amniocentesis performed on admission was negative (Gram stain negative; amniotic fluid white blood cell count, 1 cell/mm³). In view of the early gestational age (26 weeks), it was elected to continue the mother on a regimen of antibiotic therapy in an effort to prolong the pregnancy. Cervical dilatation progressed to 6 cm, and the patient underwent a cesarean section because of breech presentation 1 week later. Intraoperative uterine cultures were positive for Klebsiella pneumoniae and Streptococcus viridans. The first organism was resistant to ampicillin whereas the second demonstrated an intermediate sensitivity to this antibiotic. The placenta showed severe histologic chorioamnionitis. The neonate had multiple complications of prematurity and died after a massive grade IV intraventricular hemorrhage.

The second neonate with presumed sepsis was born to a mother with a positive cervical culture for Streptococcus agalactiae who was unresponsive to tocolysis (amniotic fluid white blood cell count, 22 cells/mm³).

The placenta showed eviderice of histopathologic chorioamnionitis. The neonate had a clinical course consistent with sepsis but recovered with antibiotic treatment.

Of the 195 patients included in the study, 156 underwent a trial of tocolysis (12 patients had a positive Gram stain and 37 were delivered for maternal or fetal indications). Fig. 4 displays a receiver-operator characteristic curve for the value of an amniotic fluid white blood cell count in the prediction of preterm labor refractory to tocolysis (area under the curve, 0.625; SE, 0.044; z=2.810; p<0.01). Table VI displays the diagnostic indices of different amniotic fluid white blood cell counts in the identification of the patients who failed to respond to tocolysis. All patients with an amniotic fluid white blood cell count ≥ 500 cells/mm³ had delivery of a preterm neonate.

The amniocentesis-to-delivery interval of patients with a positive amniotic fluid culture for mycoplasmas was significantly shorter than that of patients with sterile amniotic fluid (median, 0.8 days; range, 0 to 23.68

days vs median, 28 days; range, 0 to 122; p < 0.001; Wilcoxon rank sum test).

Comment

Our data show a strong relationship between the amniotic fluid white blood cell count and microbial invasion of the amniotic cavity. This observation can be exploited for diagnostic purposes. In our study an amniotic fluid white blood cell count of ≥50 cells/mm³ had a higher sensitivity than did the Gram stain of amniotic fluid in the detection of a positive culture (80% vs 48%, p < 0.05). The greater sensitivity of the amniotic fluid white blood cell count may be attributed to the inability of the Gram stain to detect mycoplasmas (44% [11/25] of patients with a positive amniotic fluid culture had only mycoplasmas isolated from the amniotic fluid). Indeed, only two of the 11 patients in whom mycoplasmas were the only amniotic fluid isolates had a positive Gram stain. Since mycoplasmas are not seen with a Gram stain examination, these cases represent either "false-positive" Gram stains or failure

to recover fastidious microorganisms in cases of mixed infections. On the other hand, an amniotic fluid white blood cell count ≥ 50 cells/mm³ was present in 81.8% (9/11) of patients in whom mycoplasmas were the only

The greater sensitivity of the amniotic fluid white blood cell count in the detection of a positive culture of amniotic fluid in comparison with the Gram stain was associated with a lower specificity (87.6% vs 98.8%, respectively; p < 0.05). The resulting higher falsepositive rate may be an important shortcoming of the amniotic fluid white blood cell count. However, the apparent false-positive results deserve comment. Eightyeight percent (15/17) of patients with an amniotic fluid white blood cell count ≥ 50 cells/mm³ and a negative amniotic fluid culture had premature delivery, and 66% (10/13) of them showed histologic evidence of chorioamnionitis. Therefore, independent of the culture result, an elevated amniotic fluid white blood cell count identified a subset of patients at risk for failure to respond to tocolysis and impending preterm delivery. These patients may have had microbial invasion of the amniotic cavity that escaped detection with the microbiologic surveillance techniques used in our study or, alternatively, neutrophil recruitment into the amniotic cavity may have been driven by a noninfectious process.

Five patients had false-negative amniotic fluid white blood cell counts (<50 cells/mm³) and a positive amniotic fluid culture. Three potential explanations may be invoked for these findings: (1) failure of the host to respond to microbial invasion of the amniotic cavity, (2) low virulence of microorganisms involved, or (3) a time-dependent phenomenon. If microbial invasion of the amniotic cavity is of short duration (i.e., it occurred after the onset of preterm labor), the host may not have had enough time to mount an inflammatory response. Regrettably, the relative contribution of these mechanisms cannot be addressed without data.

The white blood cell differential count has diagnostic value in peripheral blood and cerebrospinal fluid. Does it have value in amniotic fluid? Patients with a positive amniotic fluid culture had a significantly higher abso-

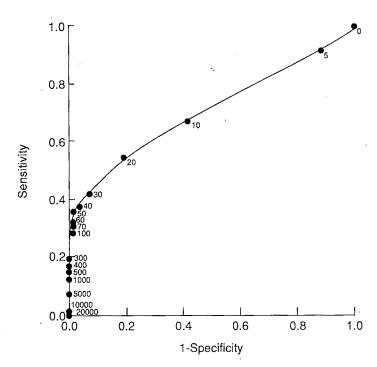

Fig. 4. Receiver-operator characteristic curve analysis of amniotic fluid white blood cell count in identification of patient who will have delivery of preterm neonate. Only patients with negative Gram stain of amniotic fluid who received tocolysis were included in this analysis. *Numbers* next to *solid dots* represent amniotic fluid white blood cell counts (cells per cubic millimeter) (area under curve, 0.625; SE, 0.044; z = 2.810; p < 0.01).

Table VI. Diagnostic indices of amniotic fluid white blood cell count in prediction of spontaneous preterm delivery

Amniotic fluid white blood cell count (cells/mm³)	Sensitivity (%)	Specificity (%)	Positive predictive value (%)	Negative predictive value (%)
≥500	12.5 (9/72)	100 (84/84)	100 (9/9)	57.1 (84/147)
≥100	27.7 (20/72)	98.8 (83/84)	95.2 (20/21)	61.4 (83/135)
≥50	31.9 (23/72)	98.8 (83/84)	95.8 (23/24)	62.8 (83/132)

lute neutrophil count than did patients with a negative amniotic fluid culture. However, we could not demonstrate any difference between the receiver-operator characteristic curves of the absolute neutrophil count and the total amniotic fluid white blood cell count (Fig. 3). The most likely explanation for this observation is that in preterm labor the neutrophil is the white blood cell most commonly recruited into the amniotic cavity (see Table II). The practical consequence of this observation is that a simple amniotic fluid white blood cell count has diagnostic value comparable to that of the absolute neutrophil count, which requires a centrifugation step, staining, and reading of the smear. However, these data do not negate the potential value of the amniotic fluid white blood cell differential. Further studies are required to address the frequency and value of other white blood cell types in the diagnosis of other intrauterine pathologic conditions (e.g., viral disease, immune-mediated phenomena, etc.).

An elevated amniotic fluid white blood cell count was not associated with clinical chorioamnionitis. This suggests that the inflammatory response was localized to the uterine cavity and did not elicit a clinically demonstrable systemic response (e.g., fever). Indeed, preterm parturition may be considered as an efficient mechanism to limit the dissemination of intrauterine infection and to prevent systemic maternal disease. We were surprised to find a low amniotic fluid white blood cell count in three of the four patients with clinical chorioamnionitis. These cases may represent extraamniotic infections (e.g., deciduitis) or clinical diagnostic errors.

The absence of proved neonatal sepsis in our study must be interpreted with caution since patients with a positive Gram stain for microorganisms were treated antepartum with antibiotics, and this may have altered neonatal culture results. Moreover, neonatal cultures for mycoplasmas, the most common microbial isolates in our study, were not performed. It is possible that a fraction of the suspected but unproved neonatal sepsis may be due to these organisms.24.25

An important additional observation of this study is that patients with microbial invasion of the amniotic cavity as a result of mycoplasmas had a significantly shorter amniocentesis-to-delivery interval than did patients with a negative amniotic fluid culture. Moreover, 81.8% (9/11) of patients with a positive amniotic fluid culture and genital mycoplasmas had an amniotic fluid white blood cell count ≥50 cells/mm³ and also had histologic evidence of chorioamnionitis (Table V). These observations indicate that microbial invasion of the amniotic cavity with mycoplasmas is associated with recruitment of white blood cells into the amniotic cavity and also with acute inflammatory lesions of the placenta. These findings, coupled with the isolation of Ureaplasma urealyticum and Mycoplasma hominis from the cerebrospinal fluid24 and bronchial secretions25 of preterm neonates who had meningitis and chronic lung disease, support a pathogenic role of these microorganisms. However, our results are at variance with those of Gravett et al.,6 who found no difference in amniocentesis-to-delivery interval between patients with sterile amniotic fluid and those with a positive amniotic fluid culture for genital mycoplasmas. Moreover, they found virtually no amniotic fluid white blood cells in patients with positive amniotic fluid cultures for genital mycoplasmas. We have no explanation for the discrepancy between the two reports.

We have examined the combined use of the amniotic fluid white blood cell count and Gram stain examination of amniotic fluid in the rapid diagnosis of microbial invasion of the amniotic cavity. Simultaneous use of both tests was associated with an increased sensitivity in comparison to that of the Gram stain alone (84% vs 48%, p < 0.05). However, this was associated with an increased false-positive rate (1.2% to 11.2%; p < 0.05). We believe this false-positive rate is more apparent than real because 88% of patients with an elevated amniotic fluid white blood cell count and a negative culture had a spontaneous preterm delivery. These findings call for caution in the use of the amniotic fluid culture as the gold standard in this type of study. A positive amniotic fluid culture requires a minimum inoculum size, viability of the microorganisms in the specimen, and successful recovery of the microorganisms in the microbiology laboratory. Moreover, microorganisms unidentified by current laboratory techniques also may be responsible for some intrauterine infections. Our data indicate that an elevated amniotic fluid white blood cell count identifies patients with microbial invasion of the amniotic cavity and a population of patients at risk for preterm delivery despite a negative amniotic fluid culture. It remains to be established if the inflammatory reaction in these patients is caused by an unidentified infectious agent or a non-infection-driven

Simultaneous use of the Gram stain and the amniotic fluid white blood cell count takes advantage of the high specificity of the Gram stain for the detection of microbial invasion of the amniotic cavity and of the high specificity of amniotic fluid white blood cell count for the prediction of preterm delivery. The patient with a negative Gram stain of amniotic fluid and a white blood cell count <50 cells/mm3 had only a 2.8% risk of having a positive culture and was at low risk for having a preterm birth (3.7%). On the other hand, a patient with a positive Gram stain of amniotic fluid and an elevated amniotic fluid white blood cell count has nearly a 100% risk of having a positive amniotic fluid culture (100% [11/11] had a positive amniotic fluid culture). In our opinion, this is an indication for antibiotic treatment and for withholding tocolytic therapy. We were unable to estimate the risk of spontaneous preterm delivery for these patients because the Gram stain was used for intervention in some patients in our study. A more difficult management problem is the patient with a negative Gram stain of amniotic fluid and a white blood cell count above 50 cells/mm3. These patients are likely to have microbial invasion of the amniotic cavity with Mycoplasmas or an extraamniotic infection (deciduitis) or an inflammatory process unrelated to infection. The development of rapid methods for the diagnosis of Mycoplasma infections can contribute to the identification of the first condition. Further studies are required to develop methods to detect deciduitis of infectious or noninfectious etiology.

We conclude that the amniotic fluid white blood cell count is a rapid, sensitive, inexpensive, and simple test for the detection of microbial invasion of the amniotic cavity and for the identification of patients at risk for spontaneous preterm delivery.

Shoulder dystocia: Should the fetus weighing ≥4000 grams be delivered by cesarean section?

Oded Langer, MD, Michael D. Berkus, MD, Robert W. Huff, MD, and Arnon Samueloff, MD

San Antonio, Texas

A total of 75,979 women who were delivered vaginally in the period 1970 to 1985 were stratified into diabetic and nondiabetic groups. Overall, the incidence of macrosomia (≥4000 gm) was 7.6% (5674/74390) in the nondiabetic group and 20.6% (328/1589) in the diabetic group. Patients were further subdivided by weight categories at 250 gm intervals. Eight percent of shoulder dystocia occurred in the diabetic group when fetal weight was ≥4250 gm. In contrast, 20% of shoulder dystocia in the nondiabetic group could have been prevented by elective cesarean section when the fetal weight was ≥4500 gm. Furthermore, logistic regression analysis demonstrated that birth weight, diabetes, and labor abnormalities were the principal contributors to shoulder dystocia. Elective cesarean section is strongly recommended for diabetics with fetal weights ≥4250 gm, and trial of vaginal delivery for nondiabetic fetuses with weights ≥4000 gm is recommended. In all cases the clinician must be watchful for labor abnormalities in macrosomic fetuses. (AM J OBSTET GYNECOL 1991;165:831-7.)

Key words: Shoulder dystocia, diabetes in pregnancy, fetal macrosomia, trauma

Shoulder dystocia is the infrequent, unanticipated, unpredictable nightmare of the obstetrician. The overall reported incidence of shoulder dystocia is 2 to 21 per 1000 births. The care provider may have limited skills to manage this catastrophe because of its infrequency.

Perinatal outcome associated with shoulder dystocia results in increased morbidity and mortality. Additionally, this clinical calamity often may be associated with disastrous medical-legal results. Therefore most authorities recommend that an elective cesarean section be performed when estimated fetal weight is ≥4500 gm. However, controversy persists on the optimum method of delivery of the fetus weighing 4000 to 4500 gm.²⁻⁴

The frequency of shoulder dystocia is believed to be higher in diabetic subjects. In spite of this fact, the majority of studies addressing shoulder dystocia failed to stratify the patient populations into diabetic and non-diabetic groups. This is a crucial omission because diabetes mellitus is an accepted risk factor for macrosomia, shoulder dystocia, and birth trauma. The rarity of shoulder dystocia has predisposed studies to smaller sample sizes that are insufficient to demonstrate the

true prevalence of shoulder dystocia within multiple fetal weight categories (Table I). Thus there have been limitations on the in-depth analysis of the magnitude of the problem, which may have affected the results reported in the studies.

Although several studies have examined the risk factors for shoulder dystocia, paucity of information exists regarding the net effect of these risk factors on diabetic and nondiabetic women. Our research addressed the question: Is cesarean section the optimum method of delivery of the fetus ≥4000 gm? The measurable objectives were to ascertain the effects and relative contribution of risk factors (by means of a logistic regression model) for diabetic and nondiabetic subjects. This would provide an estimate of the net effect of each risk factor and identify the potential high-risk pregnancies that should be monitored with greater intensity.

Material and methods

A trend study of 75,979 consecutive vaginal deliveries (fetal weight, ≥2500 gm) from 1970 to 1985 was undertaken by the Department of Obstetrics and Gynecology at The University of Texas Health Center at San Antonio. Data, consisting of medical history, demographic characteristics, obstetric complications, labor and delivery events, and neonatal outcome, were available from the computerized departmental data base.

Shoulder dystocia was defined as failure of the shoulder to be delivered after the head in spite of standard maneuvers that were based on the judgment of the clinician delivering the fetus. Diabetes mellitus included

Table I. Incidence of shoulder dystocia and associated fetal macrosomia in selected articles

NA. Not available.

pregestational and gestational individuals. Outcome measures included (1) trauma (nerve injury, fracture, and seizures), (2) pulmonary complications (meconium aspiration, pneumothorax, and neonate requiring ventilation support), (3) Apgar score < 7 at 5 minutes with division into two categories, 1 to 3 and 4 to 6, and (4) perinatal mortality.

For purpose of analysis, patients were classified into diabetic and nondiabetic groups. Patients were further stratified into birth weight categories at 250 gm intervals beginning at 3750 gm. The birth weight category between 2500 and 3749 gm served as the normal-weight reference group against which other weight categories were compared. Comparison within and between groups was performed on all categoric data by means of χ^2 and Fisher's exact tests where appropriate.

To assess the extent to which various risk factors affect shoulder dystocia, we used the logistic regression model with the BMDP statistical package (BMDP Statistical Software, 1988, Los Angeles). The resulting odds ratios indicated the net effect of a given independent variable when all other variables were controlled.

Results

Patient characteristics. During this study period 74,390 nondiabetic and 1589 diabetic patients were delivered. Overall the incidence of macrosomia (≥4000 gm) in the nondiabetic group was 7.6% (5674/74390), whereas an incidence of 20.6% (328/1589) was found in the diabetic group.

The race distribution was comparable for diabetic and nondiabetic patients; approximately 10% white, 10% black, and 80% Hispanic. Diabetic subjects were significantly older than the nondiabetic ones (28 \pm 6.5 vs 23 \pm 5.5, p < 0.0001). Additionally, more diabetic subjects were >30 years old in comparison with nondiabetic women (44.0% vs 12.7%, p < 0.0001). Multiparity accounted for 78.9% of the diabetic versus 58% for nondiabetic women (p < 0.0001).

The overall incidence of shoulder dystocia was 3.1% (range, 1.8% to 4.8%) for diabetic women and 0.5% (range, 0.4% to 0.7%) for nondiabetic women. The relative risk for shoulder dystocia was significantly higher for diabetic versus nondiabetic women (relative risk, 5.92; 95% confidence interval, 4.39 to 7.98). Further analysis revealed that the relative risk for shoulder dystocia was 2.6-fold (95% confidence interval, 1.29 to 5.34) higher for diabetic versus nondiabetic women in the weight category <4000 gm and 3.6-fold (95% confidence interval, 2.37 to 4.76) higher for diabetics when fetal weight was ≥4000 gm.

Association between fetal weight and shoulder dystocia. Overall, there was a threefold higher frequency of macrosomic infants born to diabetic than to nondiabetic mothers. Table II demonstrates the frequency of large infants within each birth weight category. As anticipated, when cases were grouped in 250 gm increments, there was an increased incidence of shoulder dystocia directly related to increased infant birth weight. With 4500 gm used as a threshold, there was a twofold higher rate of macrosomic infants in the diabetic group (33%) when compared with the nondiabetic group (16%).

The relationship between shoulder dystocia and birth weight categories revealed that approximately 40% of shoulder dystocia in the nondiabetic group occurred in infants weighing <4000 gm. In the diabetic group 84% showed evidence of shoulder dystocia with birth weights ≥4000 gm (Fig. 1).

Finally, when the incidence of shoulder dystocia was evaluated by birth percentile to control for the effect of gestational age on birth weight, it was found that 87% of the cases occurred in the ≥90th birth weight percentile for the nondiabetic and in 77% for the diabetic group. Moreover, diabetic infants had a significantly higher risk for shoulder dystocia at the 75th percentile when compared with nondiabetic infants (Fig. 2).

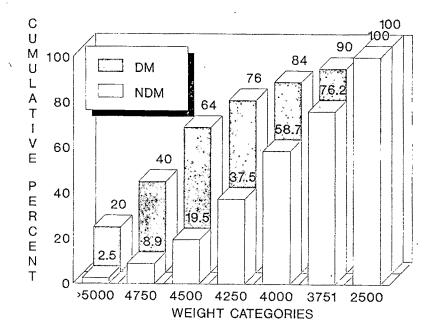

Fig. 1. Percent cumulative incidence of shoulder dystocia at or above stated birth weight for diabetic (DM) and nondiabetic (NDM) pregnant women. For each birth weight threshold ≥3751 gm, cumulative incidence of shoulder dystocia was significantly higher in diabetic subjects.

NS, Not significant.

Relationship between shoulder dystocia and pregnancy outcome. The overall relative risk for pregnancy complications (perinatal mortality, infant trauma, and low Apgar score) was 10.49-fold higher (95% confidence interval, 9.51 to 12.97) in infants with shoulder dystocia when compared with infants without shoulder dystocia. The relative risk for trauma complications was comparable for the diabetic and nondiabetic infants with shoulder dystocia. The diabetic infant had a higher relative risk for perinatal mortality and low Apgar scores when compared with the nondiabetic infant (Table III).

In the subjects with shoulder dystocia, 37% in the nondiabetic and 81% in the diabetic groups showed evidence of at least one or more complications. Among the infants with complications, comparison between the

diabetic and nondiabetic groups revealed the following: (1) that more than twice as many stillbirths occurred in the diabetic group as in the nondiabetic group (25% vs 10%), (2) that there was a comparable rate of neonatal death for both groups (5% and 4%, respectively), (3) that an Apgar score of <7 at 5 minutes showed comparable rates (47% vs 43%), and (4) that in regard to neonatal pulmonary complications similar results were obtained for both groups (7% and 10%, respectively).

The cumulative incidence for shoulder dystocia was 76%, and shoulder dystocia-related trauma was 82% for diabetic infants in the 4250 gm weight group category, with only a minimal 6% increase in the cumulative rate for shoulder dystocia at the 4000 gm category (Fig. 3, A). In contrast, in the nondiabetic group, in the 4500 gm weight category only 20% of shoulder dystocia

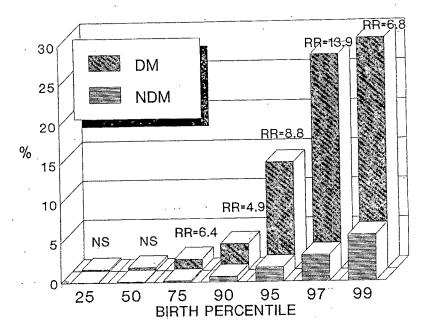

Fig. 2. Frequency of shoulder dystocia and relative risk (*RR*) in each birth weight percentile category for diabetic (*DM*) and nondiabetic (*NDM*) subjects. *NS*, Not significant.

Perinatal mortality Birth trauma Low Apgar score	28 36 38	2.2 3.5 5.8	17.21 15.47 11.06	8.51-34.83 8.17-29.28 5.90-20.44	5.2 16.3 16.3	0.6 1.5 2.9	9.53 14.05 6.40	6.98-14.94 10.72-18.43 4.92-8.39

and shoulder trauma cases were identified. Furthermore, even at 4000 gm almost 40% will go undetected (Fig. 3, B).

Finally, we compared the association between neonatal complications and shoulder dystocia and neonatal complications and shoulder dystocia-associated trauma. In general, complications showed a greater association with shoulder dystocia alone than with shoulder dystocia-associated trauma (p < 0.0001). The comparison between shoulder dystocia and shoulder dystocia and trauma revealed: (1) For pulmonary complications there was an overwhelming 86% versus 14%, respectively; (2) for Apgar scores of 1 to 3 the shoulder dystocia group showed 40% in comparison with 2% for shoulder dystocia-associated trauma with comparable rates, 48% and 9%, respectively, for Apgar scores of 4 to 6; (3) stillbirth occurred only in the shoulder dystocia group; (4) neonatal death in the shoulder dystocia group accounted for 87% and 13% in the shoulder dystocia-associated trauma group.

Identified and rank risk factors contributing to shoulder dystocia. Logistic regression analysis was used to study the effects of each factor on shoulder dystocia while the effects of all other factors were being simultaneously studied. Three analyses were performed: (1) for all the study population, (2) diabetic alone, and (3) nondiabetic alone. The results of the analyses demonstrating the net effect of each factor are summarized in Table IV. Strong associations were found for three of the 12 variables tested for the diabetic group and five of the 12 for the nondiabetic group. In general, birth weight and diabetes showed the highest ranking for increased risk for shoulder dystocia.

Shoulder dystocia and method of delivery. Table V demonstrates the theoretic net cumulative contribution to the overall cesarean section rate if all patients from that weight threshold, or greater, underwent cesarean section. For example, if all diabetic subjects whose infants weigh ≥4250 gm were delivered by cesarean section, the overall cesarean section rate would increase

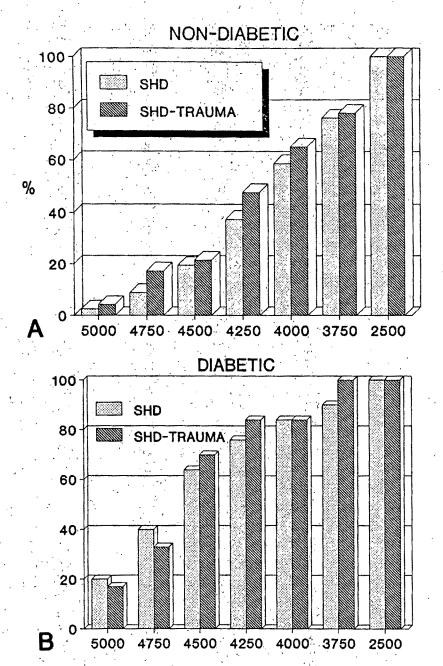

Fig. 3. A, Cumulative incidence of shoulder dystocia (SHD) alone and shoulder dystocia-trauma in each weight category for nondiabetics. B, Cumulative incidence of shoulder dystocia (SHD) alone and shoulder dystocia-trauma in each weight category for diabetics.

by only 0.26% and would result in the elimination of 76% of the cases of shoulder dystocia.

Comment

The key finding in our study is that in diabetic women approximately 80% of the cases of shoulder dystocia with and without trauma can be eliminated by cesarean section delivery, with negligible increase in the overall cesarean section rate. The current cesarean section rate in our institution is 12.5%. Using 4250 gm as the birth weight threshold for elective cesarean section delivery

in our diabetic patients will commit 158 patients to cesarean section. Of these, 24% are associated with shoulder dystocia. However, this 24% represents 76% of the total number of cases in the diabetic group. Thus, if our ultimate goal is the elimination of shoulder dystocia, prevention of 76% for the price of a fractional percentage increase in cesarean section rate appears to be justified. Notably, this represents an insignificant increase in the overall cesarean section rate of, at most, 0.26% (i.e., 12.76% cesarean section rate).

In contrast, in the nondiabetic group no definitive

weight category was identified as the optimal threshold for cesarean section delivery to decrease cases of shoulder dystocia. Even at 4000 gm, approximately half the cases will go undiagnosed and will be accompanied by an alarming increase in overall cesarean section rate of 7.5%. Moreover, the current recommended weight category of 4500 gm for elective delivery by cesarean section in nondiabetic women is questionable in light of our data. Only 20% of the shoulder dystocia cases will be prevented with the addition of 1.2% to the overall cesarean section rate. Thus the majority of cases of shoulder dystocia (80%) still remain the Pandora's box of the clinician.

Previous studies used bivariate analysis to identify risk factors contributing to shoulder dystocia. 1, 2, 4, 9 Only one study³ attempted to create a predictive model with

three-way discriminant analysis, and it was found that even the best classification failed to disclose 85% of cases. In this study we used the multivariant stepwise logistic regression model, which assigns the relative net importance of each risk factor while all other factors are kept constant. For example, a relative risk of 1.23 for the risk factor race can be interpreted to mean that when adjustment is made for certain other risk factors, black fetuses run a roughly 23% increased risk for shoulder dystocia. It was found that birth weight and the presence of diabetes were the highest risk factors for shoulder dystocia, followed by labor-related factors such as duration of labor, type of anesthesia, and type of delivery. These findings corroborate previous studies.2,4 Other variables previously designated as relevant by bivariate testing, such as parity, maternal age, fetal gender, and postdate pregnancy, failed to retain a significant relationship to shoulder dystocia in the presence of associated factors.3,7

A high complication rate of 37% was found for the nondiabetic group, and an inordinately high rate of 81% was found for the diabetic group. On comparison of each group with its relevant reference group, an increased risk ranging from 6.4 to 15.5 was found. The high incidence of complications for the nondiabetic subjects is consistent with previous reports.3,5 Shoulder dystocia is a clinical diagnosis that is based on the judgment of the clinician and, regardless of accompanying trauma, shoulder dystocia is the culprit. In our study most of the perinatal mortality and morbidity were associated with cases of shoulder dystocia without trauma. Thus shoulder dystocia should be addressed as a formidable obstetric complication, and the accessory complications should be an integral part of the diagnosis. This finding was found to be true for both diabetic and nondiabetic groups.

Our study substantiates the findings of previous studies that demonstrated that approximately 50% of the infants with shoulder dystocia weighed <4000 gm.10 Our study, which stratified subjects into diabetic and nondiabetic groups, demonstrated that the 40% shoulder dystocia rate in the nondiabetic group occurred in infants weighing <4000 gm. Approximately 87% of these infants were relatively large for their gestational age and were classified as ≥90th percentile. Our study disclosed that, in contrast to the nondiabetic subjects, only 20% of shoulder dystocia in diabetic subjects occurred in infants weighing <4000 gm. However, shoulder dystocia was a significant event for infants even at the 75th percentile. Furthermore, a sixfold higher risk for shoulder dystocia occurred in diabetic compared with the nondiabetic women at this percentile classification. Researchers performing anthropometric studies post partum on macrosomic infants described them as having a greater shoulder-head and chest-head disproportion, regardless of birth weight.11 Others, using ultrasonography on antepartum macrosomic infants, recommended the use of a macrosomic index to detect shoulder dystocia.12

In summary, shoulder dystocia and the high perinatal mortality and morbidity associated with this condition necessitate a preventive strategy. For diabetic women elective cesarean section is strongly recommended when estimated fetal weight is ≥4250 gm. This approach will eliminate 80% of cases with a minimal increase in the cesarean section rate. Unfortunately, this is not the case for nondiabetic subjects, because prevention of shoulder dystocia by elective cesarean section will leave the majority of cases undetected. Thus trial of vaginal delivery for nondiabetic fetuses with weight estimation ≥4000 gm is recommended. In these cases the clinician must heed labor abnormality indicators in the presence of the macrosomic infant.

A five-year statewide experience with congenital diaphragmatic hernia

Katharine D. Wenstrom, MD, a Carl P. Weiner, MD, and James W. Hanson, MD Iowa City, Iowa

Antenatal in utero surgery for congenital diaphragmatic hernia has been justified by reported perinatal mortality rates of 77% to 80%. Such rates may have been subject to bias of ascertainment and may include fetuses with additional severe malformations who would not be surgical candidates. We used the lowa Birth Defects Registry to conduct a complete population survey to determine the incidence of congenital diaphragmatic hernia, the frequency of associated severe malformations, and the morbidity and mortality of infants with isolated congenital diaphragmatic hernia who were not subjected to antenatal surgery. The incidence of congenital diaphragmatic hernia was 1 in 3715. Twenty-eight percent of affected fetuses had associated severe malformations that were potentially identifiable prenatally and that would have precluded antenatal surgery. Of those with isolated congenital diaphragmatic hernia, 55% survived in spite of delivery (88.5%) and/or surgical repair (44%) in a level I or II hospital. Any decision for in utero surgery to repair congenital diaphragmatic hernia must be based on this or similarly obtained information. (AM J OBSTET GYNECOL 1991;165:838-42.)

Key words: Congenital diaphragmatic hernia, in utero surgery

As techniques of fetal diagnosis and treatment have evolved, considerable attention has focused on the possibility of antenatal surgical therapy for select malformations. One potential malformation amenable to prenatal surgical correction is congenital diaphragmatic hernia.1.2 This surgery entails risks to both mother and child, with a reported fetal mortality rate of 75% (6/8) early in the development of this procedure and with associated maternal morbidity that includes chorioamnionitis, preterm labor and delivery, and the creation of an unstable uterine scar dictating repeat cesarean sections for future pregnancies.1.2 This still-experimental surgery has been justified by the reportedly high mortality rate (77% to 80%) of fetuses with congenital diaphragmatic hernia who are not treated until after birth. These rates were derived from physician surveys,3 the experience of single tertiary care centers,4-6 and infant death registries.7 Such data, however, may be biased by referral patterns3-6 and incomplete ascertainment.7 Before fetal surgery for congenital diaphragmatic hernia can be considered an appropriate

option, the natural history of this malformation must be determined as accurately as possible. We used the Iowa Birth Defects Registry to conduct a complete population survey from which we obtained information concerning the incidence and associated morbidity and mortality of congenital diaphragmatic hernia among fetuses delivered with this defect.

Material and methods

All fetuses with congenital diaphragmatic hernia who were born to Iowa residents between 1983 and 1988 were identified through the Iowa Birth Defects Registry. The staff of this registry, which is a cooperative effort involving the University of Iowa, the Iowa Department of Public Health, and the Centers for Disease Control, United State Public Health Service, confidentially investigates all infants with congenital malformations who are born to Iowa residents at >20 weeks' gestation or who weigh >500 gm. Fetuses or infants with birth defects recorded on birth certificates and/or death certificates are identified, and all hospital records (prenatal, labor and delivery, neonatal, and subsequent hospitalizations) are thoroughly reviewed on site by specially trained field representatives. Only fetuses or infants with confirmed diagnoses of congenital diaphragmatic hernia (Bochdalek or Morgagni hernias or congenital absence of the diaphragm) were included in this study.

Information obtained from each case study included maternal history, family history, prenatal course, labor and delivery events, level of the delivery hospital, level of the hospital that provided postnatal care, diagnostic

Table I. Outcome of infants with congenital diaphragmatic hernia and additional severe malformations

Malformation	No.	. Outcome
Trisomy 18	3	Stillbirths at 32.5 and 33 wk; death on 1st day of life
Trisomy 13	1	Stillbirth at 36.5 wk
Neural tube defect	3	Stillbirths at 28.5, 32, and 35.5 wk
Hypoplastic left heart	2	Stillbirths at 36 and 40 wk
Hypoplastic right heart	1	Stillbirth at 31.5 wk
Multiple malformations	1	Stillbirth at 35.5 wk
Cornelia de Lange syndrome	2	Death on 1st day of life
Pentalogy of Cantrell	1	Stillbirth at 28 wk
Aortic malformation	1	Death on 1st day of life
Cystic hygroma, hydrops	1	Stillbirth at 22.5 wk
Potter syndrome	1	Stillbirth at 39 wk
Microcephaly	I	Alive at 28 mo (seizure disorder, severe developmental delay)

tests, surgical therapy, postoperative course, autopsy findings, and follow-up. Information obtained from the registry was supplemented with direct chart review. Statistical analysis was by χ^2 and Mann-Whitney U test where appropriate. A p value of < 0.05 was considered significant.

Results

Sixty-five cases of congenital diaphragmatic hernia were discovered in 241,473 births, for an incidence of 1 in 3715. Ninety-two percent of these cases were Bochdalek hernias (78% left, 14% right), 1.5% were Morgagni hernias, and 1.5% involved complete absence of the diaphragm. The remaining 5% were classified only as "congenital."

Eighteen infants (18/65, 28%) had associated severe abnormalities (Table I). All could potentially have been identified prenatally by ultrasonography or karyotype analysis. Four of these 18 pregnancies (22.2%) were complicated by polyhydramnios. The survival rate of infants with congenital diaphragmatic hernia associated with other malformations was 5.5%. Fourteen infants were stillborn and 3 died shortly after birth. One infant with severe microcephaly survived and at 28 months had a seizure disorder, orthopedic problems, esotropia, and severe developmental delay.

In an effort to focus on potentially salvageable infants, the 17 infants whose deaths were related to associated severe malformations and the one surviving infant with severe microcephaly (who might not have been a candidate for antenatal surgery) were then excluded from the study. The remaining 47 infants were grouped according to survival (n = 26) versus nonsurvival (n = 21), and their characteristics were compared. No significant differences were found between the groups with respect to maternal age, gravidity, parity, gestational age at delivery (one preterm delivery in each group), birth weight, infant sex, hernia type, record of prenatal ultrasonography, family history of genetic problems, or pregnancy complications such as preterm labor, premature rupture of membranes, preeclampsia,

diabetes, hypertension, seizure disorder, twins, or placenta previa. The incidence of polyhydramnios was not significantly different between the groups. Five pregnancies were complicated by polyhydramnios (none of these infants were delivered preterm); one infant lived.

The cesarean section rates of infants with isolated congenital diaphragmatic hernia were similar for both groups (31% survival vs 42% nonsurvival, p = 0.72). The groups were equally likely to be delivered in a level I or level II hospital (88.5% survival vs 76% nonsurvival, p = 0.47) and to be transferred to a level III hospital (56% survival vs 72% nonsurvival, p = 0.56). One characteristic associated with a poor prognosis was the need for aggressive resuscitation of the infant at delivery (27% survival vs 100% nonsurvival, p = 0.007).

All infants with isolated congenital diaphragmatic hernia except three (in the nonsurvival group) underwent postnatal surgery. No infant received extracorporeal membrane oxygenation. Only two surviving infants, compared with 19 nonsurvivors, had severe pulmonary and cardiac problems (pulmonary hypoplasia, pulmonary hypertension, persistent fetal circulation, and dextrocardia) that were related to the hernia (p < 0.0001). Death was attributed to hernia-associated problems in 19 cases (40% of infants with isolated congenital diaphragmatic hernia) and to postoperative complications in the remaining two cases.

We attempted to determine whether the level of the delivery hospital influenced outcome. All cases were grouped according to delivery in level I or II hospitals (group 1, n = 49) or level III hospitals (group 2, n = 16; Table II). Patients in group 1 were significantly more likely to have had uncomplicated pregnancies. They were significantly less likely to have had the hernia identified antenatally by ultrasonography or to have had infants with other malformations. The survival rate between the two groups was similar.

The survival rate for infants with isolated diaphragmatic hernia was 55% (26/47). Specific long-term follow-up information was available on 13 infants (range,

3 to 48 months). The condition of 12 infants was described as excellent. One infant had seizures and developmental delay at 19 months.

Comment

The diaphragm develops from four separate structures (the septum transversum, the pleuroperitoneal membranes, the dorsal mesentery of the esophagus, and the body wall) that grow toward each other and fuse by the end of the eighth week of life. Failure of one of these structures (usually the pleuroperitoneal membranes) to grow or fuse results in a defect in the diaphragm, which allows free communication between the thoracic and abdominal cavities. When abdominal organs enter the chest through such a defect, lung development may be impeded, the heart may be displaced, and vascular structures may be distorted. It is thought that these alterations result in pulmonary hypoplasia, pulmonary hypertension, and cardiac abnormalities, although this has not been clearly demonstrated. When these abnormalities are present, they cause significant neonatal morbidity and mortality and may preclude recovery in spite of the best surgical correction at birth. Attempts have been made to define prognostic indicators of outcome, but such indicators generally have been limited to neonatal parameters.8-10 There is as yet no clear evidence that prognosis can be defined antenatally, although polyhydramnios has been associated with a poor outcome.3.4

Mortality rates associated with congenital diaphragmatic hernia have been reported to range from 24% to 95%.3,4,7,11,12 This spectrum of risk probably results from the various methods used to obtain data and from the inconsistent inclusion or exclusion of fetuses who have other malformations. The association of congenital diaphragmatic hernia with additional severe malformations in a large proportion of patients (29% to 53%) has been described, 4, 5, 11, 13 underlining the heterogeneous pathogenesis of this defect. The association of congenital diaphragmatic hernia with schisis defects, trisomies, and certain well-defined conditions such as Cornelia de Lange syndrome emphasizes the pleiotropy

of causal factors contributing to congenital diaphragmatic hernia. Because congenital diaphragmatic hernia can arise from and be associated with a variety of pathologic processes, it is not surprising that prediction of outcome has been difficult.

When other major malformations are present in association with congenital diaphragmatic hernia, they are usually directly responsible for perinatal death. Studies investigating the postnatal management of infants with congenital diaphragmatic hernia indicate that only those infants with isolated congenital diaphragmatic hernia are candidates for postnatal surgery or other therapy. When antenatal corrective surgery for such fetuses is considered, only morbidity and mortality rates from similarly affected fetuses should be used for comparison. Accurate morbidity and mortality rates from fetuses with isolated congenital diaphragmatic hernia have been previously unavailable.

Existing prevalence and outcome studies are largely flawed by biased or inadequate data collection. One study that purported to reveal the "hidden mortality" associated with congenital diaphragmatic hernia⁷ used data obtained from one major referral center and from an infant death registry. Live-born infants with congenital diaphragmatic hernia who were not referred to that center were undetected. In addition, information regarding associated anomalies, which were expected in 29% to 53% of cases, was not available for more than half the study patients. It is possible that the infants referred to the major center for surgery had isolated congenital diaphragmatic hernia, while those who either had died before transfer or were not transferred had associated malformations and would not have been surgical candidates. It is also possible that, as in certain cases in our study, some children with isolated congenital diaphragmatic hernia were successfully cared for locally. The conclusion reached by those authors, which is that the "true" mortality of congenital diaphragmatic hernia is 66%, cannot be substantiated without additional data.

Another study obtained information about outcome in congenital diaphragmatic hernia from a physician survey.3 In spite of the bias inherent in this method of data collection, the mortality rate of 80% suggested by that article has been used to justify prenatal surgery.2 This rate, however, included 15 fetuses with associated severe malformations who would not have been surgical candidates. Similar inclusion of fetuses with multiple malformations in another series yielded a mortality rate of 90.5%.4 Although that series was biased by data collection techniques (all cases were cared for at one referral center), 9/19 fetuses (47%) in this series had associated severe malformations that would have precluded surgical therapy. Only a complete population survey in which all infants born with congenital diaphragmatic hernia are identified and evaluated for . associated anomalies will yield accurate prognostic data about the outcome for fetuses with this defect.

Because the Iowa Birth Defects Registry identifies all infants who are born with a congenital malformation at >20 weeks' gestation or who weigh >500 gm, stillbirths, neonatal deaths, and surviving infants are identified regardless of physician, hospital of birth, or subsequent treatment. Our estimated prevalence of 1 in 3715 is similar to that reported by a large British study (1/3030)14 and is actually higher than the 1 in 5455 reported by Harrison et al.7

Twenty-eight percent of infants in our series had associated severe malformations, the spectrum of which was similar to that reported in other series. All were theoretically prenatally identifiable by means of ultrasonography or karyotype analysis, and none of those infants would have been candidates for prenatal surgery. Cases such as these must be excluded from statistical analysis when the background mortality rate for congenital diaphragmatic hernia is used as a rationale for antenatal therapy.

The survival rate among the 47 cases of isolated congenital diaphragmatic hernia in our survey was 55%. Eighty-five percent (40/47) were delivered in level I or II hospitals, and 43% underwent surgery for repair at a level I or II hospital. None was treated with extracorporeal membrane oxygenation. The choice of delivery hospital was probably related to many factors but was undoubtedly strongly influenced by the high incidence of apparently uncomplicated pregnancies and by the lower rate of prenatal detection of the hernia in the group delivered at level I or II hospitals. Because routine obstetric ultrasonography was not common at the time of this study (and others), it is possible that the infants with prenatal diagnosis and referral to a tertiary care center for delivery were those with the most antenatal complications and therefore the worst prognoses. The infants whose gestations were relatively uncomplicated appeared to have a similar survival rate in spite of delivery at non-tertiary-level hospitals, although this lack of a statistical difference may represent a type II error. Recent data suggest that survival among infants with isolated congenital diaphragmatic hernia can be increased from 50% to 76% with the use of extracorporeal membrane oxygenation and other aggressive postdelivery management. 12, 15 It is likely that some of the nonsurvivors who were delivered at level I or II hospitals may have benefited from this treatment. As antenatal ultrasonography becomes more common, similar infants with congenital diaphragmatic hernia and otherwise uncomplicated pregnancies will be identified much more often before delivery. Antenatal diagnosis as the serendipitous result of routine ultrasonography probably does not have the same prognostic significance as does diagnosis made during the evaluation of polyhydramnios or other pregnancy complications. The temptation to consider antenatal surgery in these salvageable infants will be strong, but these infants are the ones most likely to respond to aggressive neonatal management and they are the most likely to survive without in utero surgery.

Our study also emphasizes the skewed data that are likely to be generated from patients referred to a tertiary care center. The distribution of cases in our series suggests that such centers see the most compromised fetuses with the worst prognoses. Fetuses with relatively uncomplicated congenital diaphragmatic hernia are more likely to be cared for locally and without the aid of specialty consultants.

Finally, it is possible that there is a subset of infants with isolated congenital diaphragmatic hernia who would benefit from antenatal surgery. In our series 40% of infants with the isolated defect died because of hernia-associated problems. If these infants could somehow be distinguished antenatally, they would be the most logical candidates for surgery. Presently, this determination is not possible.

In summary, our population-based study determined that the survival rate for infants with isolated congenital diaphragmatic hernia was 55%. If these infants had been identified prenatally, referred to a tertiary care center, and aggressively managed at birth, their survival rates might have been even better. In utero surgery probably has a future, but it should be reserved for fetuses whose anomalies predict lethal outcomes if not repaired antenatally. Those fetuses with congenital diaphragmatic hernia who would benefit from such surgery need to be clearly identified, and techniques must be developed to distinguish them from their lower-risk cohorts before antenatal repair is offered.

Intrapartum ultrasonographic estimates of fetal weight by the house staff

Deborah N. Platek, MD, Michael Y. Divon, MD, Akolisa Anyaegbunam, MD, and Irwin R. Merkatz, MD

Bronx, New York

In spite of the widespread use of ultrasonographic estimates of fetal weight, a paucity of data exists with regard to its use in patients who are in labor. The purpose of this study was to evaluate the accuracy of ultrasonographic estimates of fetal weight in a busy labor and delivery suite by the house staff.

Measurements of biparietal diameter, abdominal circumference, and femur length were prospectively obtained in 109 patients in labor in whom this information was expected to be contributory in making delivery plans. All patients were delivered within 48 hours of ultrasonographic evaluation. Measurements of abdominal circumference were obtained in all cases, Biparietal diameter and femur length were obtained in 85% and 92% of cases, respectively. Overall, the mean absolute errors were 9.3% and 9.2% for estimated fetal weight by biparietal diameter/abdominal circumference/femur length ratios, respectively. Estimated fetal weight by biparietal diameter/abdominal circumference ratio was not significantly different from that by femur length/abdominal circumference ratio. In conclusion, the accuracy of intrapartum estimates of fetal weight performed by the house staff in a busy labor and delivery unit is comparable to that reported for estimates obtained during the antepartum period by professional users of ultrasonography in a controlled setting. (AM J OBSTET GYNECOL 1991;165:842-5.)

Key words: Estimated fetal weight, ultrasonography, house staff

Ultrasonography, since its introduction in the 1960s, has provided a "window" into the uterus. Early technology enabled the evaluation of fetal number and the site of placentation. With the advent of gray-scale ultrasonography fetal structure was more easily delineated, and it became possible to diagnose morphologic abnormalities antenatally. In addition, measurements

of head, trunk, abdomen, and extremities have established a set of norms for gestational age that is indispensable for accurate dating and assessment of adequate growth in utero. Real-time ultrasonography has provided the ability to assess the fetus in its own minuteto-minute environment. Observations of fetal activity and response to various stimuli have created new insight into the universe of the developing human.

In the 1970s investigators proposed using ultrasonography to obtain estimates of fetal weight. A variety of formulas were evaluated, including cephalometry, serial parallel scans of the entire length of the fetus, thoracic and abdominal circumferences, diameters or cross-sectional areas, and various combinations of these measurements.14

The formulas most often used are logarithmic derivatives of multivariate regression analysis that are based on biparietal diameter and abdominal circumference⁵ and on abdominal circumference and femur length.6 These formulas became popular because of the ease in obtaining these measurements and the accuracy of the estimate generated. Both models report a systematic error of ≤10% relative to the actual birth weight.

A precise estimate of fetal weight may be an important factor in the evaluation of patients in labor. Accurate clinical estimate of fetal size by palpation of the abdomen is a function of the experience of the examiner and can be influenced by the size and shape of the patient. It has been shown that clinical estimates of fetal weight are most inaccurate in the extremes of fetal weight—very large or very small fetuses.7.8

Most studies of the accuracy of ultrasonographic fetal weight estimates have had the measurements performed by professional users of ultrasonography in a laboratory setting. In many institutions, however, a trained ultrasonographer is not always available at the time management decisions need to be made. In addition, a bedside sonogram obtained from a patient in active labor can be technically challenging.

In a busy inner-city hospital with a resident-run labor floor, decisions are often made on the basis of an ultrasonographic scan obtained by the admitting resident. It is important to know how accurate these estimates are and how much they can be relied on in the care of the patient. Therefore the purpose of this study was to evaluate the accuracy of ultrasonographic estimates of fetal weight performed by residents in an acute-care setting.

Material and methods

This study was conducted prospectively from January through July 1990 on the labor floor of the Bronx Municipal Hospital Center. Ultrasonographic evaluation was performed by the admitting resident whenever

Table I. Indications for testing

	No.	%
Premature rupture of membranes	19	17.4
Preterm labor	15	13.7
Suspected macrosomia	14	12.8
Small for dates	10	9.2
Uncertain dates	11	10.2
Vaginal bleeding	14	12.8
Breech	12	11.0
Twins	6	5.5
Other	8	7.4
TOTAL	109	100

it was thought that an ultrasonographic estimate of fetal weight would aid in the management of labor. Only patients with a live fetus, with no known anomalies, and in active labor were included in this study.

Ultrasonographic scans were performed by thirdand fourth-year residents using the Ultramark IV (ATL, Inc., Tempe, Ariz.) dynamic image scanner with a 3.5 MHz linear transducer. Electronic caliper measurements of the biparietal diameter, abdominal circumference, and femur length were made with the use of defined landmarks. Estimates of fetal weight were calculated by computer-generated regression equations as per Shepard et al.5 and Hadlock et al.6 The mean and absolute error percentages defined as

$$\frac{\text{(Birth weight - Estimated weight)}}{\text{Birth weight}} \times 100$$

were used for comparison of estimates.

Results

A total of 109 patients were entered in the study and 115 sets of measurements were obtained (i.e., 103 singleton gestations and six sets of twins). All patients were delivered within 48 hours, 76 (60.3%) within 12 hours and 93 (85%) within 24 hours. Birth weight (mean \pm SD) was 2701 \pm 915 gm.

The leading indications for ultrasonographic evaluation were fetal growth abnormalities, premature rupture of the membranes, and preterm labor representing 22%, 17.4%, and 13.7% of measurements, respectively (Table I).

Measurement of the abdominal circumference was obtained for all fetuses. In 16 patients (15%) a biparietal diameter could not be obtained because of technical difficulties. Similarly, femur length was not obtained in nine (8%) fetuses scanned. The inability to obtain a biparietal diameter or a femur length was distributed throughout the different indications for testing, with somewhat fewer measurements of both biparietal diameter and femur length in patients with suspected macrosomia (five of 25 absent measurements) and uncertain dates (6/25).

A total of 205 estimates were generated (99 estimates

Table I	. Distrib	ution of	absolute	error e	of 115	fetal	weight	estimates
---------	-----------	----------	----------	---------	--------	-------	--------	-----------

Estimated fetal weight	Within 5% of birth weight (%)	Within 10% of birth weight (%)	Within 15% of birth weight (%)	>20% of birth weight (%)
By biparietal diameter/abdominal circumference	35.7	60	78.5	10.2
By abdominal circumference/femur length	39	60.9	81	10.5

Table III. Mean absolute error (%)

	Birth weight				
Estimated fetal weight	<2500 gm (%)	2500-4000 gm (%)	>4000 gm (%)		
By biparietal diameter/abdominal circumference	$ \begin{array}{c} 10.8 \\ (n = 40) \end{array} $	8.7 $(n = 50)$	7.1 $(n = 8)$		
By abdominal circumference/femur length	$9.6 \\ (n = 43)$	9.3 $(n = 53)$	$ \begin{array}{c} (n = 9) \\ \end{array} $		

by biparietal diameter/abdominal circumference, and 106 estimates by femur length/abdominal circumference). Sixty percent of these estimates were within 10% of the actual birth weights for each of these methods. The estimates were within 5% of birth weight in 35.7% of those calculated from biparietal diameter/abdominal circumference and in 39% of those calculated with abdominal circumference/femur length. These differences were not significant (Table II).

The mean errors for estimated fetal weight by biparietal diameter/abdominal circumference and femur length/abdominal circumference were 9.3% and 9.2%. There was no statistical difference between the two formulas. The mean overall error was 10.1% in the fetuses whose birth weights were <2500 gm, 9.0% in the fetuses whose birth weights were between 2501 and 4000 gm, and 7.0% in the fetuses whose birth weights were >4000 gm (Table III).

The birth weight was <1500 gm in 13 patients who were enrolled in this study. The mean birth weight was 1046 gm (range, 590 to 1390 gm). The mean estimated fetal weight calculated by biparietal diameter/abdominal circumference was 1033 gm (range, 535 to 1452 gm), and the mean error was 10.9%.

Estimates of fetal weight were obtained in 19 fetuses with a diagnosis of premature rupture of membranes. The mean errors were 10.5% for estimated fetal weight by biparietal diameter/abdominal circumference and 9.4% by abdominal circumference/femur length.

Comment

There have been numerous studies investigating the accuracy of the ultrasonographic methods of estimating fetal weight. Most investigators report a mean absolute error ranging between 8.0% and 13.8% of birth weight. The results of this study indicate that a similar mean absolute error (9.3%) can be obtained by the house staff

in an acute-care setting. The mean absolute error for the very-low-birth-weight babies was comparable to that seen for the general population.

The estimated fetal weight by biparietal diameter/abdominal circumference was reported separately by Warsof et al., Timor-Tritsch et al., and Shepard et al. Their studies report a range of 54% to 72.5% of estimated fetal weights that were within 10% of the actual birth weights. This is comparable to the 60% of patients in our study who had estimated fetal weights within 10% of birth weights.

The studies of Hadlock et al.⁶ and Yarkoni et al.¹¹ show a mean error for the use of estimated fetal weight by femur length/abdominal circumference measurements that is ≤4%. The results of our study show a similar accuracy with a mean error of 1.2%.

Most studies of estimated fetal weight have been conducted in the antepartum period. Ultrasonographic study of patients in labor presents some unique problems, including both patient discomfort caused by uterine contractions and the operator's discomfort caused by the contorted position necessary for him or her to perform a bedside ultrasonographic examination. It has been suggested that measurement of the biparietal diameter in labor may be unreliable or unobtainable because of fetal skull engagement and molding. ¹² Our findings suggest that only a small percentage (15%) of measurements of biparietal diameter could not be obtained in this study population.

Of interest are the patients scanned with premature rupture of membranes. Other studies report an underestimation of fetal weight with oligohydramnios associated with rupture of membranes. This was not reflected in this study, where the error was 10.5% for estimated fetal weight by biparietal diameter/abdominal circumference and 9.4% for estimated fetal weight by abdominal circumference/femur length; however,

this subgroup of our patient population was relatively

In conclusion, the results of this study indicate that the accuracy of intrapartum estimates of fetal weight by the house staff in a busy labor and delivery unit is comparable to that reported by skilled operators in more controlled settings.

The cheek-to-cheek diameter in the ultrasonographic assessment of fetal growth

Jacques S. Abramowicz, MD, David M. Sherer, MD, Eli Bar-Tov, PhD, and James R. Woods, Jr., MD

Rochester, New York

Deviations from normal growth modify the amounts of adipose tissue and muscle mass in the adult and the fetus. As an index of the amount of adipose tissue in the fetus, the cheek-to-cheek diameter obtained on an ultrasonographic coronal view of the face at the level of the nostrils and lips was evaluated. Two hundred thirty-four singleton uncomplicated, well-dated pregnancies ranging from 20 to 41 weeks were studied. Two hundred fetuses with biometric measurements or estimated weights between the 10th and 90th percentile for gestational age were included in obtaining a nomogram. Cheek-to-cheek diameter as a function of gestational age was expressed by the regression equation: Cheek-to-cheek diameter (centimeters) = -0.908 + 0.195 Gestational age (gestational age ≥ 20 weeks), with a Pearson correlation coefficient of $R^2 = 0.806$. The cheek-to-cheek diameter/biparietal diameter ratio was almost constant, independent of gestational age, and ranged from 0.6 at 20 weeks to 0.7 at 41 weeks. Fetuses with intrauterine growth retardation tended to have lower ratios. Macrosomic fetuses of diabetic mothers had larger cheek-to-cheek diameters and elevated ratios, whereas large-for-gestational-age fetuses of nondiabetic mothers had normal ratios. (AM J Obstet Gynecol 1991;165:846-52.)

Key words: Ultrasonography, fetal growth, nomogram, cheek-to-cheek diameter

Multiple ultrasonographic parameters have been used to evaluate fetal growth and nutritional status with varying degrees of success. In infants, measurements of subcutaneous fat in the flank, forearms, or thighs are currently used as clinical indexes for signs of deviation from normal growth. 2.3

It is common knowledge that poor nutritional status is reflected by sunken cheeks, whereas individuals with increased weight will have an overall larger deposition of adipose tissue in their bodies, and in their cheeks in particular. Studies in which fetal subcutaneous tissues have been evaluated by radiography and correlated to weight have revealed retarded fetal growth to be associated with decreased fat thickness.⁴

Our study was designed to indirectly evaluate by ultrasonography amounts of subcutaneous adipose tissue in fetuses by measuring the distance between the cheeks (cheek-to-cheek diameter) in uncomplicated gestations and to establish a nomogram of the cheek-to-cheek diameter in relation to gestational age. Furthermore, we examined the validity of the measurements in a small

sample of fetuses with abnormal growth (intrauterine growth retardation [IUGR] or macrosomia).

Material and methods

Two hundred thirty-four patients referred to Strong Memorial Hospital, the regional perinatal center, for routine ultrasonography were examined with commercially available real-time equipment with 3.5 or 5 MHz transducers (AI 5200, Acoustic Imaging, Phoenix, Ariz.; ATL Ultramark 9, ATL, Bothell, Wash.; Aloka 650, Aloka 280, Corometrics Medical Systems, Inc., Wallingford, Conn.). Only uncomplicated singleton pregnancies were included. Gestational age was obtained from a well-defined last menstrual period with confirmation by early ultrasonography, before 20 weeks. Gestational age ranged from 20 to 41 weeks. Fetal measurements included cheek-to-cheek diameter, biparietal diameter, head circumference, abdominal circumference, and femur length. The cheek-to-cheek diameter was obtained on a coronal view of the fetal face at the level of the nostrils and lips (Figs. 1 and 2). Very rarely, because of shadowing, the distal cheek could not be clearly visualized. In these cases the distance from the proximal cheek to the middle of the mouth was measured and multiplied by two (Fig. 3). This was used in only five cases in the derivation of the regression equation. Estimated fetal weight was obtained from biparietal diameter and abdominal circumference measurements.5 Only fetuses between the 10th and 90th percentile by biometry or estimated fetal weight were included in establishing a nomogram

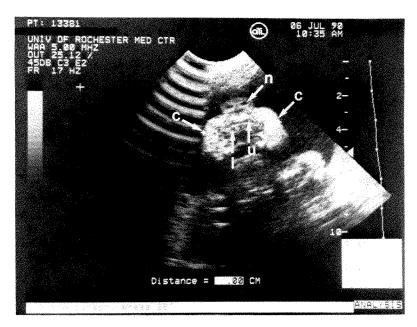

Fig. 1. Coronal view of fetal face at $27\frac{1}{2}$ weeks' gestation. Nostrils (n), lips (upper, u; lower, l), and cheeks (c) are evident. Markers represent cheek-to-cheek diameter.

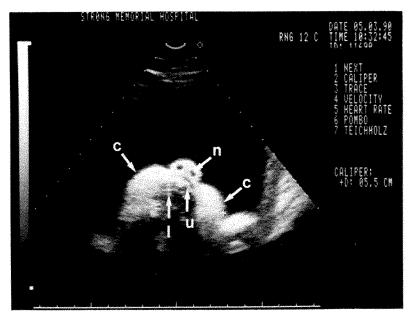

Fig. 2. Cheek-to-cheek diameter at 31% weeks' gestation. Nostrils (n), lips (upper, u: lower, l), and cheeks (c) are evident. Markers represent cheek-to-cheek diameter.

(N = 200). All deliveries occurred after 37 completed weeks, and no infants had evidence of growth disturbance (IUGR or macrosomia) or congenital anomalies. One measurement per fetus was recorded, thus providing cross-sectional data. Twenty fetuses had multiple measurements for interobserver and intraobserver error analysis: After a cheek-to-cheek diameter was obtained by one observer, the picture was frozen and measurements were taken. A second observer then performed measurements on the frozen image without knowledge of the previously obtained value. The picture was then unfrozen and a new cheek-to-cheek diameter was selected. A hard copy was then taken and measurements were performed by two independent observers. An evaluation was also made of the feasibility of the technique by trying to obtain a cheek-to-cheek diameter for every single obstetric ultrasonography performed between 20 and 41 weeks' gestational age during a 1-week period. Measurements were difficult to obtain before 20 weeks, but this probably is not of

Fig. 3. Distal cheek is not clearly visualized. Measurement of one-half cheek-to-cheek diameter at 34% weeks' gestation. *Central marker* lies beneath fetal nasal septum.

primary clinical importance because the fetus gains 95% of its weight in the last 20 weeks of gestation.

The data were analyzed with the SAS and Minitab programs. Correlation between cheek-to-cheek diameter and biparietal diameter, estimated fetal weight, and gestational age were studied with Pearson correlation coefficients. Regression analysis was performed,

and the best-fit equations for cheek-to-cheek diameter and the cheek-to-cheek diameter/biparietal diameter ratio as a function of gestational age and gestational age as a function of cheek-to-cheek diameter were obtained. Confidence intervals corresponding to ± 2 SD (i.e., 95% of the population; 2.5% being above and 2.5% below normal limits) were established.

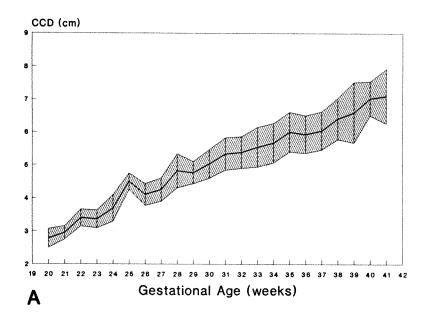

After nomograms were derived, measurements of cheek-to-cheek diameter and cheek-to-cheek diameter/biparietal diameter ratios in large-for-gestationalage (LGA) fetuses (biometry or estimated fetal weight, >90th percentile) and small-for-gestational-age (SGA) fetuses (biometry or estimated fetal weight, <10th percentile) were obtained for comparison purposes. LGA fetuses were separated into those of diabetic or non-diabetic mothers. Another category examined was appropriate-for-gestational-age (AGA) fetuses of diabetic mothers.

Results

The growth of the cheek-to-cheek diameter during pregnancy was found to be linear from 20 to 41 weeks. The linear regression equation as function of gestational age was:

$$CCD = -0.908 + 0.195 \text{ GA } (GA \ge 20 \text{ weeks})$$

where CCD is cheek-to-cheek diameter in centimeters and GA is gestational age in weeks. The coefficient of correlation (Pearson) was $R^2 = 0.806$. Table I represents predicted cheek-to-cheek diameters at different gestational ages, including mean \pm 2 SD. Fig. 4 is the graphic representation of these data. The upper part

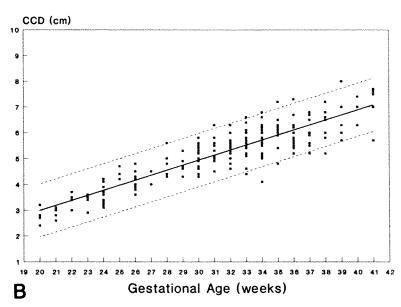

Fig. 4. Cheek-to-cheek diameter as a function of gestational age. **A,** Observed mean \pm 2 SD. **B,** Predicted mean by regression equation \pm 2 SD. *Squares,* Individual data pairs.

represents the observed mean (± 2 SD) and the lower part, the equation-predicted mean ± 2 SD with the scattergram of data pairs superimposed. The equation of gestational age as a function of cheek-to-cheek diameter was:

$$GA = 9.77 + 4.16 CCD$$

where CCD is cheek-to-cheek diameter and GA is gestational age (with the same coefficient of correlation). Table II represents the predicted gestational age with the mean \pm 2 SD, as derived from the cheek-to-cheek diameter for selected values. Pearson correlation coefficients (R^2) for cheek-to-cheek diameter as a function of gestational age, biparietal diameter, and estimated

fetal weight were 0.807, 0.756, and 0.767, respectively. The regression equation for the cheek-to-cheek diameter/biparietal diameter ratio as a function of gestational age was:

CCD/BPD =
$$0.47 \pm 0.0066$$
 GA (GA ≥ 20 weeks)

where CCD is cheek-to-cheek diameter and GA is gestational age.

Therefore the ratio ranged from 0.6 at 20 weeks to 0.74 at 41 weeks (mean ± 2 SD = 0.68 ± 0.1), i.e., gestational age has very little influence on the ratio in normal pregnancies within the above-mentioned gestational age. Table III and Fig. 5 represent the normal values and the diagrammatic representation of the data

for the cheek-to-cheek diameter/biparietal diameter ratio (upper and lower part, as in Fig. 4).

The cheek-to-cheek diameters of 10 fetuses with IUGR were compared with those of 200 normal fetuses

by t test for unpaired data. A trend was demonstrated for smaller cheek-to-cheek diameters in IUGR, but numbers were too small to attain statistical significance (p=0.74). The same held true for the cheek-to-cheek diameter/biparietal diameter ratio (p=0.8). Mean values of the cheek-to-cheek diameter and the cheek-to-cheek diameter/biparietal diameter ratios for LGA fetuses are shown in Table IV. Cheek-to-cheek diameters of LGA fetuses were consistently larger than those of AGA fetuses, with LGA fetuses of diabetic mothers having very significantly larger cheek-to-cheek diameters and cheek-to-cheek diameter/biparietal diameter ratios than all other fetuses. Measurements in AGA fetuses of diabetic mothers were not different from fetuses of nondiabetic mothers (controls).

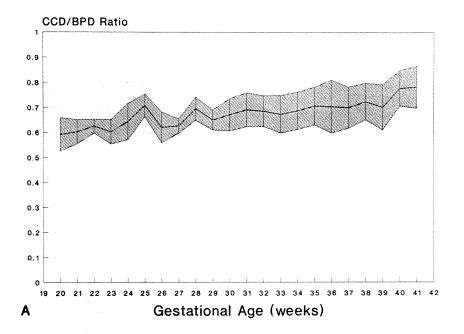

Cheek-to-cheek diameter was obtained in 70% of cases. Only when the fetus was directly occipitoanterior (face down) was it impossible to obtain the appropriate image. Often waiting a few minutes or having the patient return after a short interval permitted the appropriate visualization.

Interobserver and intraobserver error calculation demonstrated the reproducibility of the method, with both observers being reliable and their results not statistically different from each other on the same image or comparing images obtained separately at different time intervals. (Paired t test p values for interobserver and intraobserver variability were 0.32 and 0.58, respectively).

Comment

Our results demonstrate that in normal pregnancies the cheek-to-cheek diameter is directly correlated with gestational age. The cheek-to-cheek diameter/biparietal diameter ratio is almost age independent in fetuses with normal growth, varying from 0.6 to 0.74 between 20 and 41 weeks' gestation.

Multiple fetal organs have been measured by ultrasonography to follow growth or weight or to evaluate gestational age, from the early biparietal diameter more than 20 years ago to fetal long bones and, recently, clavicles. Most measurements involve bony structures or body parts as a reflection of the growth of the internal organs (abdominal or chest circumference, for instance). In infants the adequacy of intrauterine nutrition has been evaluated by measurements of the arm circumference³ or skin-fold thickness.⁸ Thigh circumference has been used as an index of amounts of soft tissues to estimate fetal growth.9 Subcutaneous fat has been observed radiographically in the fetus and has been correlated with weight. Jeanty et al.2 demonstrated that limb volume is a function of the amount of adipose tissue and is strongly correlated with gestational age. However, these authors point out that because of technical limitations and overlapping values of

^{*}Mean gestational age.

subcutaneous tissue thickness, this measurement is a poor predictor of growth and is useful only in extreme cases.

Fetal cheeks have been previously identified by ultrasonography with clear visualization of the anatomically defined corpus adiposum buccae, Bichat's fatpad.¹⁰ This is the area that we chose to measure to obtain the cheek-to-cheek diameter, because it is mainly formed of white fat that is sensitive to changes in nutritional status.6 Excessive body size is caused by skeletal frame enlargement and, to a larger degree, by more abundant body fat mass. This is particularly demonstrated in infants of diabetic mothers.8 Maternal diabetes induces accelerated fetal growth in insulin-sensitive tissues. 6, 11 Because the brain is not insulin-sensitive, cephalic growth is not affected. Somatic growth of the fetal abdomen and other body areas with subcutaneous adipose tissue is affected. Therefore the macrosomic infant of a diabetic mother has an asymmetrically large body in relation to head size. These infants are "bulkier" than infants of the same weight born to nondiabetic mothers. 12, 13 The detection of fetal macrosomia is possible by ultrasonography. 12 Recently, macrosomia in the infant has been described as different, depending on whether the mother is diabetic,13 with certain indexes, such as femur length/abdominal circumference ratio, being very helpful in the differentiation.14 This concept has been challenged by authors,15 as has the clinical usefulness of the femur length/abdominal circumference ratio in predicting macrosomia in fetuses of diabetic mothers.16 At the other side of the scale, gestational age-independent indices are also needed to identify SGA fetuses.

In our study, mean values of the cheek-to-cheek diameter were larger in LGA than in AGA fetuses, particularly in LGA fetuses of diabetic mothers. LGA fetuses of diabetic mothers could be differentiated by their having a cheek-to-cheek diameter/biparietal diameter ratio significantly larger than controls, while the ratio in LGA fetuses of nondiabetic mothers fell in the normal range. In our small sample of IUGR fetuses, the cheek-to-cheek diameter and the cheek-to-cheek diameter/biparietal diameter ratio demonstrated a trend toward being smaller, suggesting a reduction in the amount of subcutaneous fat in the fetal cheeks. A longitudinal study of the cheek-to-cheek diameter is currently in progress.

In conclusion, when precise gestational age is known, cheek-to-cheek diameter measurements can help in the follow-up of fetal growth. In cases with less than certain gestational age, cheek-to-cheek diameter is less useful, but a normal cheek-to-cheek diameter/biparietal diameter ratio is a reassuring index of adequate growth.

We express our appreciation to Laura E. Ayers and Sean B. Logghe of the Perinatal Computer Center at the University of Rochester School of Medicine and Dentistry for their help with the statistical analysis and graphic representation of the data, and to Susan A. Smith, RDMS, Tamara A. Allen, RDMS, Paula C. Eggers, RDMS, Bobbi Hearn-Stebbins, RDMS, and Lenore Liberto, RDMS, for their help with ultrasonography data collection.

Only TRI-NORINYL starts your OC patients with The TRI-NORINYL Total Health Program.™

When you start your OC patient with The TRI-NORINYL Total Health Program sample package, you provide the benefits of oral contraception *plus* an exciting new patient-support program.

The TRI-NORINYL Total Health Program sample package contains one cycle of TRI-NORINYL; the attractive Wallette® Pill Dispenser; and a patient Q&A booklet—plus the video and instruction guide, The ACOG Balanced Fitness Workout; and program membership.

The TRI-NORINYL Total Health Program provides a variety of fitness and health information to help women achieve healthier lifestyles.

As part of that goal, Syntex Laboratories is proud to be a sponsor of the American Medical Association's Women's Health Campaign.

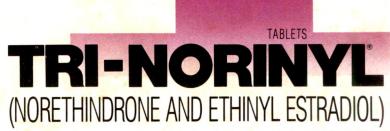

For details about The TRI-NORINYL Total Health Program, please contact your Syntex Representative.

Serious as well as minor side effects have been reported following the use of oral contraceptives. These include thromboembolic disease.

Please see adjacent page for brief summary of prescribing information.

ORAL CONTRACEPTIVE AGENTS: BRIEF SUMMARY

DESCRIPTION

TRI-NORINY, 21-DAY Tablets provide a notal contraceptive regimen of 7 blue tablets followed by 9 yellow-green tablets and 5 more blue tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg and each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg.

TRI * **TRI **** **TRI *** **TRI **** **TRI *** **TRI **** **TRI *** **TRI **** *

TRI-MORINYL 28-DAY Tablets provide a continuous oral contraceptive regimen of 7 blue tablets, 5 yellow green tablets, 5 more blue tablets, and then 7 orange tablets. Each blue tablet contains norethrodrom 6.5 mg and Hermy estradiol 0.035 mg, each yellow green tablet contains norethrodrome 1 mg and ethinyl estradiol 0.035 mg, and each orange tablet contains inert

INDICATIONS AND USAGE

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use these products as a method of contraception.

CONTRAINDICATIONS

Oral contraceptives should not be used in women who have the following conditions. Thrombophleibits or thromboembolic disorders • A past history of deep vein thrombophleibits or
thromboembolic disorders • Cerebral vascular or coronary artery disease • Known or suspected
carcinema of the breast • Carcinema of the endometrium, and known or suspected
estrogendependent neoplasus • Undiagnosed abnormal genital bleeding • Cholestatic, jourdice of pregnancy or joundice with prior pill use • Hepatic adenomas, carcinomas or benign liver tumors •
Known or suspected pregnancy

WARNINGS.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side organics showing increases our list of services carnovascular size effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia and gallbladder disease, although the risk of serious morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperipidemias, hypercholes terolemia, obesity and diabetes.

Practitioners prescribing oral contraceptives should be familiar with the following information

The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with formulations containing 0.05 mg or higher of estro-gen. The effects of long-term use with lower dose formulations of both estrogens and progestogens remain to be determined.

Proughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure case control studies and prospective of conord studies. Lose control studies provide a measure of the relative risk of a disease. Relative risk, the ratio of the incidence of a disease among oral contraceptive users to that among non-users, cannot be assessed directly from case control studies, but the odds ratio obtained is a measure of relative risk. The relative risk does not provide information on the actual clinical occurrence of a disease. Chort studies provide not a measure of the relative risk but a measure of attributable risk, which is the difference in the incidence of disease between eral contraceptive users and non-users. The attributable risk does provide information about the actual occurrence of a disease in the population

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS

1. Introducemental biodiscretain and other moderate interest and other moderate.

An increased risk of myocardial infarction has been attributed to oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery discases such as hypertension, hypercholestenlering, montiod obestly and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be 2 to 6. The risk is very low under the age of 30. However, there is the possibility of a risk of cardiovascular discase goals in our women ownens who take and nontraceptives.

is a large production and age of so, inweets, like its like possibility of a list of anounascular disease even in very young women who take oral contraceptives. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women 35 or older, with smoking accounting for the maintity of excess cases

Mortality rates associated with circulatory disease have been shown to increase substantially rs over the age of 35 and non-smokers over the age of 40 among women who use oral

Oral contraceptives may compound the effects of well-known risk factors for coronary artery one contraceptives may compound the effects of wear-anominst factors or commany areity diseases, such as hyperfension, disbets, hyperfindings, hypercholemia, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and impair oral glucose oblerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see WARNINGS, section 9). Similar effects on risk factors have been associated with an increased risk of heard disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

h. Thromboambolism

b. Thromboembolism
An increased risk of thromboembolic and thrombotic disease associated with the use of oral
contraceptives is well established. Case control studies have found the relative risk of users
compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 10
for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for owner with prefision
conditions for venous thromboembolic disease. One cohort study has shown the relative risk to
be somewhat lower, about 3 for new cases (subjects with no past history of venous thrombosis
or vancose venish and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears
after nell use is chosed. after pill use is stopped.

arter jun user is suppeu.

A2 to 6-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. If feasible, oral contraceptives should be discontinued at least 4 weeks prior to and for 2 weeks after elective surgery and during and following prolonged immobilization. Since the immediate postpartum period also is associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than 4 to 6 weeks after delivery in women who elect not to breast feed.

c. Cerebrovascular diseases

An increase in both the relative and attributable risks of cerebrovascular events (thrombot) An increase in born the relative and attributable risks of ceretrovascular events (thromobolic and hemorrhagic strokes) has been shown in users of oral contraceptives. In general, the risk is greatest among older (>35 years), Inypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users for both types of strokes while smoking interacted to increase the risk for hemorrhapic strokes.

interactive to increase the risk in humanizing, access and in a large study, the relative risk of thomobic strokes has been shown to range from 3 for nor indensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who used oral contraceptives, 1.8 for nor smokers who used oral contraceptives, 1.8 for nor

who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with swere hypertension. The attributable risk also is greater in women 35 or older and among smokers.

d. Dose-related risk of vascular disease from oral contraceptives. A postive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (RDU) has been reported with some progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase RDU cholesteroit, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogens used in the contraceptive. The amount of both hormones should be considered in the choice of a neal contraceptive.

Minimizing exposure to estrogen and progestogen is in keeping with good principles of

therapeutics. For any particular estrogen/progestogen combination, the dosage regimen pre-scribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing the lowest estrogen content that produces satisfactory results for the individual.

e. Persistence of risk of vascular disease

e. Persistence of risk of vascular disease There are three studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for al least 9 years for women 40–49 years who had used oral contraceptives for 5 or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Birtain, the risk of developing cerebrovascular disease persisted for al least 6 years after discontinuation of oral contrace-ptives, although excess risk was very small. Subaractinoid hemorrhage also has a significantly increased relative risk after termination of use of oral contraceptives. However, these studies were performed with oral contraceptive formulations containing 0.05 mg or higher of estrogen.

were performed wind under contracteptive unautous containing upon in gind in right or estrogen.

2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE

One study gathered data from a variety of sources which have estimated the mortality rates associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits. pregnancy in the event of method failure. Each method of contraception has its specific been-fits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smake and 40 and older who do not smake, mortality associated with all methods of birth control is low and below that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral contraceptive users is based on data gathered in the 1975s—but not reported in the U.S. until 1983. However, current clinical practice involves the use of lower settingen does formulations combined with careful in startchon of oral contra-ceptive use to women who do not have the various risk factors listed in this labeling.

ceptive use to women who do not have the various risk hadros istein it his isbeling. Because of these changes in practice and, also, because of some limited new data which sug-gest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1999. The Committee concluded that although cardiovascular dis-ease risks may be increased with oral contraceptive use after age 40 in healthy non-smoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical proc-dures which may be necessary if such women do not have access to effective and acceptable means of contraception. means of contraception.

Therefore, the Committee recommended that the benefits of oral contraceptive use by healthy non-smoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE ORGANS
Numerous epidemiological studies have been performed on the incidence of breast, endome
trial, ovarian and cervical cancer in women using oral contraceptives. The evidence in the liter ature suggests that use of oral contraceptives is not associated with an increase in the risk of dure suggests and use or one contractives as the age and parity of first use or with most of the mar-keted brands and doses. The Cancer and Sterrid Hormone study also showed no latent effect on the risk of breast cancer for all teast a decade following long-term use. A first subties have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and non-users and differences in age at start of use, has been questioned. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use.

Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there con-tinues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between oral contraceptive use and breast or cervi-cal cancers, a cause and effect relationship has not been established.

4. HEPATIC NEOPLASIA

Benign hepatic adenomas are associated with oral contraceptive use although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases per 100,000 for users, a risk that increases after 4 or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

Studies in the United States and Britain have shown an increased risk of developing hepatocel-lular carcinoma in long-term (> 8 years) oral contraceptive users. However, these cancers are extremely rare in the United States and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users is less than 1 per 1,000,000 users

5. OCULAR LESIONS

There have been clinical case reports of retinal thrombosis associated with the use of oral con-Traceptives. Oral contraceptives should be discontinued if there is unexplained partial or com-plete loss of vision; onset of proplosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY

b. Onat. Continue the continue of the property of the continue that is received in the continue that is the con

concerned, when taken inadvertently during early pregnancy.

The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion.

It is recommended that for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued if pregnancy is confirmed.

J. BALLBLADDER DISEASE Earlier studies have reported an increased lifetime relative risk of galibladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the rela-tive risk of developing galibladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS

8. CARBONYDRATE AND LIPID METABOLIC EFFECTS
Oral contraceptives have been shown to impair oral glucose tolerance. Oral contraceptives containing greater than 0075 mg of estrogen cause glucose intolerance with impaired insulin secretion, while lower doses of estrogen may produce less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives.

Some women may develop persistent hypertriglyceridemia while on the pill. As discussed ear-lier (see **WARNINGS**, sections 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users.

9. ELEVATED BLOOD PRESSURE

An increase in blood pressure has been reported in women taking oral contraceptives. The inci-dence of risk also was eported to increase with continued use and among older women. Data from the Rayal Cellege of General Practitioners and subsequent randomized trais have shown that the incidence of hypertension increases with increasing concentrations of progestogens. Women with a history of hypertension or hypertension-related diseases or renal disease should be encouraged to use another method of contraception. If women elect to use oral contrace-tives, they should be monitored closely and if significant elevation of blood pressure occurs oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives and there is no difference in the occurrence of hypertension among ever- and never-users.

10. HEADMANE

The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of

11. BLEEDING IRREGULARITIES

Breakthrough bleeding and spotting are sometimes encountered in patients on a tives, especially during the first 3 months of use. Non-hormonal causes should b and adequate diagnostic measures taken to rule out malignancy or pregnancy in breakthrough bleeding, as in the case of any abnormal vaginal bleeding, if pathol excluded, there or change to another formulation may solve the problem. In the e orthea, pregnancy should be ruled out.

Some women may encounter post-pill amenorrhea or oligomenorrhea, especiall a condition was pre-existent.

PRECAUTIONS 1. PHYSICAL EXAMINATION AND FOLLOW-UP

 PHI STOCKE Comment for A map to Policiary
 A complete medical history and physical examination should be taken prior to the
 reinstitution of oral contraceptives and at least annually during use of oral c
 These physical examinations should include special reference to blood pressure, t
 men and pelvic organs, including cervical cytology and relevant laboratory test undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate dia unes should be conducted to rule out malignancy. Whomen with a strong family his cancer or who have breast nodules should be monitored with particular care.

2 LIPIN NISARNERS

2. LIPPO DISTRUCKS.
Women who are being treated for hyperlipidemias should be followed closely if the oral contraceptives. Some progestogens may elevate LDL levels and may render I hyperlipidemias more difficult.

3. LIVER FUNCTION

It jaundice develops in any woman receiving oral contraceptives the medicati discontinued. Steroid hormones may be poorly metabolized in patients w

Oral contraceptives may cause some degree of fluid retention. They should be pri-caution, and only with careful monitoring, in patients with conditions which mi

5. EMOTIONAL DISORDERS

Women with a history of depression should be carefully observed and the drug di depression recurs to a serious degree.

6. CONTACT LENSES

Contact lens wearers who develop visual changes or changes in lens tolerand assessed by an ophthalmologist.

DRUG INTERACTIONS

Reduced efficacy and increased incidence of breakthrough bleeding and menst tes have been associated with concomitant use of rifampin. A similar associatio marked, has been suggested with habiturates, phenylbutazone, phenytoin sodiu bly with griseofulvim, ampicillin and tetracyclines.

8. INTERACTIONS WITH LABORATORY TESTS

Certain endocrine and liver function tests and blood components may be afficontraceptives:

Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin

norepinephrine-induced platelet aggregability
b. Increased thyroid binding globulin (TBG) leading to increased circulating tota
mone, as measured by protein-bound iodine (PBI), 14 by column or by radiominur
13 resin uptake is decreased, reflecting the elevated TBG. Free 14 concentration c. Other binding proteins may be elevated in serum

d. Sex steroid binding globulins are increased and result in elevated levels of tot sex steroids and corticoids; however, free or biologically active levels remain unc

Set introductions in the continuous interests and the continuous and t gnificance if a woman becomes pregnant shortly after discontinuing oral contri

10. PREGNANCY

Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS

Small amounts of oral contraceptive steroids have been identified in the milk of ers and a few adverse effects on the child have been reported, including jaundic enlargement. In addition, oral contraceptives given in the postpartum period may i lactation by decreasing the quantity and quality of breast milk. If possible, the nu should be advised not to use oral contraceptives but to use other forms of contra she has completely weaned her child. INFORMATION FOR THE PATIENT See PATIENT LABELING.

ADVERSE REACTIONS

An increased risk of the following serious adverse reactions has been associated of eral contraceptives (see **WARNINGS** section): Infrombophilebitis - Arterial t isim - Pulmonary embolism - Myocardial infarction - Cerebral hemorrhage - Ceresis - Hypertension - Galibladder disease - Mepatic adenomas, caraniomas or

There is evidence of an association between the following conditions and the use ϵ ceptives, although additional confirmatory studies are needed: Mesenteric thron nal thrombosis

nat thromosiss. The following adverse reactions have been reported in patients receiving oral or and are believed to be drug-related. Nausea * Vornting * Gastromtestinal symptic abdominal cramps and bloating) * Breakthrough bleeding * Spotting * Change in me. Amenorrhea * Temporary infertility after discontinuation of treatment * Edem. which may persist * Breast changes: tenderness, enlargement, secretion * Change incervical erosion and secretion * Disminution when given immediately postpartum * Cholestatic jaundice * Migraine * Rash (all tal depression * Reduced tiderance to carbohydrates * Vaginal candidiasis * Chan curvature (steepening) * Intolerance to contact lenses

The following adverse reactions have been reported in users of oral contracept association has been neither confirmed nor refuted. Pre-menstrual syndrome - Changes in appetite - Cystiths-like syndrome - Headache - Nervousness - Dizzm ism - Loss of Skalp hair - Erythema multiforme - Erythema nodosum - Hemorrhag Vaginitis • Porphyria • Impaired renal function • Hemolytic uremic syndrome • Bud ime • Acne • Changes in libido • Colitis

OVERDOSAGE

Serious ill effects have not been reported following acute ingestion of large dose: traceptives by young children. Overdosage may cause nausea, and withdrawal b occur in females.

NON-CONTRACEPTIVE HEALTH BENEFITS

The following non-contraceptive health benefits related to the use of oral contra supported by epidemiological studies which largely utilized oral contraceptive containing estrogen doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of Effects on menses: • Increased menstrual cycle regularity • Decreased bloc decreased incidence of iron deficiency anemia • Decreased incidence of dysmeno Effects related to Inhibition of ovulation: • Decreased incidence of functional ova

Decreased incidence of ectipic pregnancies

Effects from long-term use:

Decreased incidence of fibroadenomas and fibrocy
of the breast

Decreased incidence of acute pelvic inflammatory disease

Decreased incidence of acute pelvic inflammatory disease of acute pelvic inflammatory disease of acute pelvic dence of endometrial cancer . Decreased incidence of ovarian cancer

The GORE-TEX Surgical Membrane— Configured for Peritoneal Reconstruction protects denuded areas while healing progresses beneath the material.

n Peritoneal

...The GORE-TEX® Surgical Membrane The Choice in Peritoneal Reconstruction

Successful peritoneal reconstruction following pelvic surgery in the female requires dependable measures to establish the continuity of the peritoneum and the normal anatomy of the pelvic area.

Medical literature reports the use of an inert, nonabsorbable barrier as an attractive means of approaching this goal.

Performance by Design

Composed of the inert biomaterial expanded polytetrafluoroethylene (e-PTFE), the GORE-TEX Surgical Membrane limits tissue attachment with an extremely small pore size (<1µ). The nonabsorbable GORE-TEX Surgical Membrane is a physical barrier that remains in place to protect denuded areas as healing is completed, unlike absorbable materials, which provide a limited time of protection.

The GORE-TEX Surgical Membrane has a long record of safety and effecti It has demonstrated reliability among cardiac surgeons for more than 14 y addition, use in multicenter clinical studies continues to substantial safety and the invariant performance of the GORE-TEX Surgical Meml

Convenient

Available in specific configurations tailored for peritoneal reconstruction; the GORE-TEX Surgical Membrane — *Configured for Peritoneal Reconstructic* is packaged sterile and **can be resterilized**.

Choose the GORE-TEX Surgical Membrane for invariant performance in peritoneal reconstruction. To receive further information or to consult with an application specialist, call **800-437-8181**. For orders and overnight delivery 24 hours a day, call **800-528-8763**.

Modern medicine's answer to normal memory loss.

A lively and authoritative review of the year's best journal literature.

Let's face it. Remembering everything from the hundreds of articles you read is a herculean task. You're bound to forget a few important details. It's normal. It's healthy. But with a subscription to the *Year Book of Obstetrics and Gynecology*, it's also unnecessary.

Each year, the *Year Book of Obstetrics and Gynecology* brings you the most important articles relating to obstetrics and gynecology. The articles, chosen by our distinguished editors, are abstracted into concise one and two page summaries for quick and efficient reading. Nearly every article is accompanied by personal commentary from the editors discussing its significance to your daily practice.

The *Year Book of Obstetrics and Gynecology* — it's the best way to remember what you shouldn't forget.

☐ Yes! I want an overview of the year's most important journal literature.

Please send my **30-day FREE examination** copy of the *1991 Year Book of Obstetrics and Gynecology* (22118) by Daniel R. Mishell, Jr. If I decide to keep the book I'll pay \$57.95 plus shipping and handling.

riphasil Levonorgestrel and ethinyl estradiol tablets-

THE OC TO START WITH BECAUSE SHE'LL STAY WITH IT

IN BRIEF:
TRIPHASIL.** — 6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol; 7 light-green tablets containing inert ingredients are included in the 28-day regimen! — Triphasic regimen.

Indications and Usage — TRIPHASIL.** is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (0Cs) as a method of contraception.

Contraindications — OCs should not be used in women with any of the following: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebits or thromboembolic disorders. 2. A past history of deep-vein thrombophlebits or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Endometrial carcinoma or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contra-ceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

ceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

Use of CCs is associated with increased risks of serious conditions including myocardial infarction, thrombomboism, stroke, hepatic neoplasia, galibladder disease, and hypertension, although risk of serious morbidity/mortality is very small in healthy women without underlying risk factors. Morbidity/mortality risk increases significantly if other risk factors present (i.e. hypertension, hyperipidemias, besity, diabetes). Practitioners prescribing CCs should be familiar with the following information relating to these risks. This information is based principally on data involving OCs with higher doses of estrogen and progestogen than those commonly used today. Effect of long-term use of lower estrogen and progestogen formulations is yet to be determined.)

1. Thromboemboiic Disorders and Other Vascular Problems — MYOCARDIAL INFARCTION (MI). An increased risk of MI has been attributed to OC use. Risk is primarily in smokers or women with other underlying risk factors for coronary-artery disease (i.e. hypertension, hypercholesterolemia, morbid obesity, diabetes). Relative risk of heard attack for current OC users is estimated to be two to six, risk is very low under the age of 30. Smoking combined with OC use contributes substantially to incidence of MIs in women in their mid-thirties or older with smoking accounting for majority of excess cases. Mortality rates associated with circulatory disease increase substantially in smokers over the age of 30 and nonsmokers over the age of 40 among OC users.

OCs may compound effects of well-known risk factors such as hypertension, diabetes, hypertipidemias, age and obesity, in particular, some progestogens decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperisualinism. OCs have been shown to increase brook

The dosage regimen prescribed should contain the least amount of estrogen and progestogen compatible with a low failure rate and individual patient needs. Start new acceptors on preparations containing less than 50 mcg of

iow failure rate and individual patient needs. Start new acceptors on preparations containing less than 50 mcg of estrogen.

PERSISTENCE OF RISK OF VASCULAR DISEASE. Two studies have shown persistence of vascular disease risk for ever-users of OCs. In a U.S. study, MI risk after OC discontinuation persists for at least 9 years in women 40-49 years who had used OCs for five or more years; increased risk was not demonstrated in other age groups. In a study in Creat Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after OCs stopped, although excess risk was very small. Both studies used OC formulations with 50 micrograms or higher of estrogens.

of estrogens.

2. Estimates of Mortality from Contraceptive Use — A study using data from several sources concluded that with the exception of OC users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is less than that associated with childbirth. The possibility of increased mortality isk with age for OC users is based on data from the 1970s — but reported in 1983. However, current practice involves use of lower estrogen dose formulations combined with careful restriction of OC use to women without the various risk factors listed in this labeling. Changes in practice and new data suggesting that cardiovascular disease risk with OCs may be less than previously observed prompted the Fertility and Maternal Health Drugs Advisory Committee to review the topic in 1989. The Committee concluded that although cardiovascular-disease risks may be increased with OC use after age 40 in healthy nonsmokers leven with newer low-dose formulations), greater potential health risks are associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if effective, acceptable contraception is not available.

The Committee concluded that the benefits of OC use by healthy nonsmoking women over 40 may outweigh the possible risks. Older women, as all women who take OCs, should use the lowest possible effective dose formulations.

formulation.

3. Carcinoma of the Reproductive Organs — Numerous epidemiological studies have looked at the incidence of breast, endometrial, ovarian and cervical cancer in women using OCs. Overwhelming evidence suggests that OC use is not associated with an increase in risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on breast cancer risk for at least a decade following long-term use. A few studies show a slightly increased relative risk of developing breast cancer, although the methodology of these studies, including differences in examination of users and nonusers, and in age at start of use, has been questioned.

Some studies suggest that OC use is associated with an increased risk of cervical intraepithelial neoplasia in some populations of women. However, controversy continues about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between OC use and breast and cervical cancers, a cause and effect relationship has not been established.

A Hepatic Neoplasia — Benign hepatic adenomas are associated with OC use, although incidence is rare in the U.S. Indirect calculations estimate attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

British studies have shown an increased risk of hepatocellular carcinoma in long-term (> 8 years) OC users, these cancers are extremely rare in the U.S. and attributable risk (excess incidence) of liver cancers in OC users approaches less than one per million users.

5. Ocular Lesions — There are clinical case reports of retinal thrombosis with OC use. Discontinue OCs if there is unexplained partial or complete loss of vision, onset of proptosis or diplopia, papilledema, or retinal vascular lesions; undertake appropriate diagnostic and therapeutic measures immediately.

lesions: undertake appropriate diagnostic and therapeutic measures immediately
6. Oral-Contraceptive Use Before or During Early Pregnancy — Extensive epidemiological studies revealed no
increased risk of birth defects when OCs used prior to pregnancy. Studies do not suggest a teratogenic effect,
particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently
during early pregnancy. OC induced withdrawal bleeding should not be used as a pregnancy test Do not use
OCs during pregnancy to treat threatened or habitual abortion. Rule out pregnancy if two consecutive periods
missed before continuing OC use. If patient has not adhered to prescribed schedule, consider pregnancy at time
of first missed period. Discontinue OC if pregnancy confirmed.
7. Gallbladder Disease — Earlier studies reported an increased lifetime relative risk of gallbladder surgery in users
of OCs and estrogens, more recent studies show that the relative risk of developing galibladder disease among
OC users may be minimal, which may be related to use of formulations with lower hormonal estrogen and
progestogen doses.

progestogen doses.

progestogen doses.

8. Carbohydrate and Lipid Metabolic Effects — OCs cause glucose intolerance in a significant percentage of users. OCs with greater than 75 µg of estrogen cause hyperinsulinism; lower estrogen doses cause less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance; leffect varies with different agents). Observe prediabetic and diabetic women carefully while taking OCs. In non-diabetic women, OCs have no apparent effect on fasting blood glucose.

8. small proportion of women will have persistent hypertriglyceridenia while on OCs. Changes in serum triglycerides and lipoprotein levels have been reported in OC users (see Warnings).

9. Elevated Blood Pressure — Increase in blood pressure has been reported in women on OCs; increase is more likely in older OC users and with continued use. Data show that incidence of hypertension increases with increasing quantities of progestogens.

Ecourade women with history of hypertension or hypertension-related diseases, or renal disease to use another.

increasing quantities of progestogens.

Encourage women with history of hypertension or hypertension-related diseases, or read disease to use another contraceptive method. Monitor hypertensive women electing to use OSc closely, discontinue OC if significant blood pressure elevation occurs. For most women, elevated blood pressure returns to normal after OC stopped. No difference in occurrence of hypertension among ever- and never-users exists.

10. Heardace—Discontinue OC and evaluate cause at onset or exacerbation of migraine, or if new pattern of headache (i.e. recurrent, persistent, severe) develops.

11. Bleeding Irregularities—Breakthrough bleeding and spotting sometimes occur especially during first 3 months of use. Type and dose of progestogen may be important. Consider non-hormonal causes and take adequate diagnostic measures to rule out malignancy or pregnancy in event of breakthrough bleeding, as with any abnormal vaginal bleeding. If pathology excluded, time or a formulation change may solve the problem. In the event of amenorrhea, rule out pregnancy. Some women encounter post-pill amenorrhea or oligomenorrhea.

Precautions

Precautions

event of aniethoriteat, this out pregnancy. Some women encounter post-pili amenormea of oligomenormea, especially when such a condition was pre-existent.

Precautions

1. Physical Examination and Follow Up.—A complete medical history and physical examination should be taken prior to initiation or reinstitution of OCs and at least annually during use. Physical examination should be taken prior to initiation or reinstitution of OCs and at least annually during use. Physical examination should be special reference to blood pressure. Deress a adorner and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, conduct appropriate diagnostic measures to rule out malignancy. Monitor women with strong family history of breast cancer or who have breast notules with particular care. 2. Liquid Disorders.—Follow women being treated for hyperipidemias closely if they elect to use CCs. Some progestogens may elevate LDL levels and may render control of hyperipidemias more difficult. See Warningsi 3. Liver Function.—Discontinue OC it jaundice develops. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. Fluid Retention — OCs may cause some degree of fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions possibly aggivared by fluid retention. 5. Emotional Disorders.—It significant depression occurs stop medication and use alternate contraceptive method in attempts to determine if symptom is drug related. Observe carefully those with history of depression and stop drug if depression necurs to serious degree. 6. Contact. Lenses—Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. Drug Interactions—Reduced efficacy and increased increace of breakthrough bleeding and menstrual irregulanties are associated with concomitant rifampia use. A similar association, though less marked. Is suggeste

compretely wearned

Information for the Patient — See Patient Package Labeling.

Adverse Reactions — An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis; arterial thromboembolism; pulmonary embolism; myocardial infarction; cerebral hemorrhage; cerebral thrombosis, hypertension; gallibladder disease; hepatic adenomas or benign

There is evidence of an association between the following conditions and OC use, although additiona confirmatory studies are needed: mesenteric thrombosis; retinal thrombosis.

confirmatory studies are needed: mesenteric thrombosis; retinal thrombosis.

The following adverse reactions have been reported in patients on OCs and are believed to be drug-related: nausea; vomiting; gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; amenormea; temporary infertifity after treatment discontinued; edema; melasma which may persist breast changes: tenderness, enlargement; secretion; change in weight fincrease or decrease); change in cervical erosion and secretion; diminution in lactation when given immediately postpartum; cholestatic jaundice, migraine; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in OC users and the association is neither confirmed nor refuterd congenital anomalies; orgenestical syndrome; catagets, ordine querifis changes in apostite, custific like.

The following adverse reactions have been reported in OC users and the association is neither confirmed nor refuted: congenital anomalies; premenstrual syndrome; cataracts, optic neuritis; changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsuitism; loss of scalp hate, erythema multiforme; entrema nodosum; hemorrhagic eruption; vaginitis; porphyria; impaired renal function; hemolytic uremic syndrome; budd-Chiari syndrome, actre; changes in libido; colitis, sickle-cell disease; cerebral-vascular disease with mitral valve prolapse, lupus-like syndromes.

Dverdosage—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Noncontraceptive Health Benefits—The following noncontraceptive health benefits related to OC use are supported by epidemiological studies that largely utilized OC formulations containing doses exceeding 0.035 mg of thinly distradiol or 0.05 mg of mestranol. **Effects or mensural cybic regularity, bedereased blood loss and decreased incidence of iron-deficiency anemia; decreased incidence of dysmenorma. **Effects related to inhibition of ovulation;* decreased incidence of tectopic pregnancies. **Effects from long-term use: decreased incidence of the preast; decreased incidence of acute pelvic inflammatory disease; decreased incidence of endometrial cancer; decreased incidence of acute pelvic inflammatory disease; decreased incidence of endometrial cancer; decreased incidence of acute pelvic inflammatory disease; decreased incidence of endometrial cancer; decreased and **Administration**—For maximum contraceptive effectiveness, take TRIPHASIL** (levonorgestrel

Dosage and Administration — For maximum contraceptive effectiveness, take TRIPHASIL* (levonorgestrel and ethinyl estradiol tablets — triphasic regimen 21- and 28-day regimens) exactly as directed and at intervals not over 24 hours.

not over 24 flutus. (If TRIPHASI): 's first taken later than first day of first menstrual cycle of medication or postpartum, contra-ceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.) For full details on dosage and administration see prescribing information in package insert.

Transforming growth factor- β_1 expression during placental development

Lauren J. Dungy, MD, Tariq A. Siddiqi, MD, and Sohaib Khan, PhDb Cincinnati, Ohio

Placental growth has several malignant characteristics, including properties of invasiveness, rapid cell proliferation, and a lack of cell contact inhibition. These malignant characteristics of placental development are strictly regulated throughout normal gestation, because placental growth is limited in both extent and duration. Transforming growth factor- β_1 inhibits growth of many normal and malignant cell lines. In this study, using Northern blot analysis, we found transforming growth factor- β_1 expression to occur in human placenta throughout gestation. Peak expression was noted at midgestation (near 17 weeks) and again in late gestation (near 34 weeks). Immunohistochemical analysis localized transforming growth factor- β_1 protein expression to the syncytiotrophoblastic layer. The process of trophoblastic invasion of the decidua and myometrium is usually complete by 18 weeks of gestation, and absolute growth of the placenta ceases in late gestation (near 35 weeks). The time frames of maximal transforming growth factor- β_1 expression noted in our studies correlate with these events. We speculate that peak transforming growth factor- β_1 expression at these stages of placental development is suggestive of its regulation of both trophoblastic invasion and proliferation. (AM J OBSTET GYNECOL 1991;165:853-7.)

Key words: Transforming growth factor- β_1 , human placenta

Placental implantation and subsequent growth and development have been described as a pseudomalignant process. Similarities between trophoblastic cell growth and malignant cells include invasiveness, rapid cell proliferation, lack of cell contact inhibition, and a degree of immune privilege. These malignant characteristics of placental development appear to be strictly regulated throughout normal gestation, because placental growth is limited in both its extent and duration. In fact, during embryogenesis and placentation tissues and organs develop in a sequential pattern, implying that genes coding for particular proteins are turned on and off in a precise and well-regulated manner. It is now becoming apparent that growth inhibitors play an important role in maintaining tissue homeostasis. Peptide growth factors, active in common regulatory pathways, may be important regulators of placental development.

Transforming growth factor- β_1 (TGF- β_1) is a poly-

peptide originally identified in tumor cells and postulated to be involved in transformation and neoplastic growth. Its presence in numerous tissues,1-4 however, implies a normal physiologic role that appears to be multifunctional. TGF- β_1 has been shown to stimulate growth of some cell types but to inhibit growth of others, to stimulate growth of fibroblasts and promote wound healing,5.6 and to induce differentiation of leukemic and bronchial epithelial cell lines.7.8 A fundamental property of TGF-β₁ is its ability to inhibit proliferation of both normal and malignant cell lines. TGF- β_1 has been shown to inhibit growth of different ovarian cancer cell lines, as well as some human leukemic cell lines.^{8,9} As such, we hypothesized that TGF-β₁ may play an important role in the inhibition of trophoblastic invasion of the myometrium during placental development. In humans, this process is largely limited to the eighth week through the eighteenth week of gestation.10 We evaluated the temporal expression of TGF- β_1 in human placenta to begin to examine this hypothesis.

Material and methods

Collection of placental tissue. Placental tissue was obtained after curettage, spontaneous delivery, or cesarean section and immediately placed in liquid nitrogen. Informed consent was obtained from patients in all instances, in accordance with the protocol approved by our institutional review board. Time frames of placental tissue studied were chosen to correlate with early, mid, and late gestation. Placental tissue obtained from a total of 20 patients was used for analysis. Initially, a

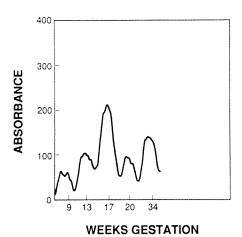

Fig. 1. Graph showing results of scanning densitometry of blots of five representative RNA samples. TGF- β_1 expression is noted throughout gestational period shown, with peak expression at 17 and 34 weeks' gestation.

panel of total ribonucleic acid (RNA) from placental tissues ranging from 6 to 40 weeks' gestation was studied with Northern blot analysis. These studies were repeated with total RNA from different placental tissues of similar gestational ages. Three panels of RNA were studied. Additionally, Northern blot analysis was performed with 100 µg of total RNA from placental tissue of 15 through 19 weeks' gestational age and 32 through 34 weeks' gestational age to further evaluate time frames where peak expression had previously been identified.

RNA isolation. Total RNA was isolated from the placental tissues according to the technique of Chomzynski and Sacchi.11 Briefly, approximately 2 gm of placental tissue was homogenized in 10 ml extraction solution (4 mol/L guanidine thiocyanate; 25 mmol/L sodium citrate, pH 7.0; 0.5% sarcosyl; 0.1 mol/L 2-β-mercaptoethanol; 2 mol/L sodium acetate; and 10 ml phenol). The homogenate was mixed with chloroform/isoamyl alcohol (2 ml of 49:1 solution) and chilled on ice for 15 minutes. After centrifugation for 20 minutes at 10,000 g at 4° C, the aqueous phase was removed and precipitated with one volume of isopropanol at -20° C for 2 hours. This was followed by a second centrifugation for 20 minutes at 10,000 g at 4° C. The resultant pellet was dissolved in extraction solution (600 μl) and precipitated with isopropanol (1:1, vol/vol) and sodium acetate (1:10, vol/vol) at -20° C for approximately 2 hours. After centrifugation for 10 minutes at 4° C, the pellet was washed with 70% ethanol and vacuum dried for approximately 5 minutes. The pellet was then resuspended in diethylprocarbonate-treated water. Total RNA concentration was quantitated by absorption spectrophotometry at 260 nm.

Northern blot analysis. RNA samples (100 µg) were

resolved by electrophoresis on formaldehyde agarose gels and transferred to nitrocellulose membranes by towel blotting. The integrity and quantity of each RNA sample were ensured by staining the gel with ethidium bromide and visualizing the gel under ultraviolet transillumination. The filters were prehybridized in hybridization solution containing 10× Denhardt's solution, 0.1% sodium dodedecyl sulfate, 100 µg/ml single standard sperm deoxyribonucleic acid, 50% deionized formamide, and a $5 \times$ solution of 3 mol/L sodium chloride, 0.1 mol/L sodium phosphate, 0.02 mol/L ethylenediaminetetraacetic acid, and sodium hydroxide and then hybridized in the same solution containing a phosphorus 32-labeled human TGF-β₁ complementary deoxyribonucleic acid probe (1 \times 10% counts/min/ml) at 42° C overnight. After four washings (final wash 1× saline sodium citrate buffer with 0.1% sodium dodedecyl sulfate at 55° C for 20 minutes) the filters were subjected to autoradiography. The position of 18S and 28S RNA was determined, and the single band observed, which corresponded to the position of TGF-β₁ messenger RNA (mRNA) (2.1 kb), was quantitated by scanning densitometry with a Hoefer GS 300 (Hoefer Scientific Instruments, San Francisco) gel

Our initial studies with 25 and 50 μg of total RNA revealed expression only at 17 and 34 weeks' gestation. In later blots TGF- β_1 expression was noted at all time points when 100 μg of total RNA was used. For this reason 100 μg samples were used in all experiments reported in this study.

Immunohistochemical analysis. Placental sections (10 µm) from 17 and 34 weeks' gestation were fixed in chilled methanol, followed by fixation in sodium periodate, lysine, and paraformaldehyde solution. The sections were then incubated at room temperature with a phosphate-buffered saline solution containing bovine serum albumin (1%) and 0.1% Triton-X-100 (Fischer Scientific, Fair Lawn, N.J.) compound for 10 minutes, followed by a 30-minute incubation with phosphatebuffered saline solution containing 0.2% gelatin to minimize background contamination. The sections were then incubated with polyclonal rabbit antibody against human TGF-B₁ (1:50 dilution in phosphate-buffered saline solution-bovine serum albumin) for 1 hour at 37° C. TGF-β₁ antibody used in this study was obtained from Collagen Corporation, Palo Alto, Calif. After three washings with phosphate-buffered saline solution containing 0.2% gelatin for 15 minutes each, the specimens were incubated with fluorescein-conjugated goat anti-rabbit polyclonal antibody (1:50 dilution in phosphate-buffered saline solution—bovine serum albumin) for 45 minutes at 37° C. After three washings in phosphate-buffered saline solution containing 0.2% gelatin, immunofluorescent sites were visualized in an epiflu-

orescence microscope (Leitz, Wetzler, Germany). Sequential sections were treated in a similar manner with nonimmune rabbit serum substituted at the same concentration for TGF- β_1 antibody to serve as control.

Results

With Northern blot analysis and 100 µg of total RNA, we were able to identify TGF-β, mRNA expression throughout the gestational ages studied (6 through 40 weeks). Fig. 1 represents the continuous scanning densitometry graph of a blot of equal amounts of total RNA isolated from placental tissue ranging from 9 to 34 weeks' gestation. Expression of TGF-β, was noted throughout the time points examined, with peaks of expression noted at 17 and 34 weeks' gestation. This is consistent with our initial findings of TGF-β₁ mRNA expression only at 17 and 34 weeks' gestation using lower amounts of total RNA (25 and 50 μg).

Northern blot analysis of total RNA isolated from tissue samples ranging from 15 to 19 weeks' gestation revealed TGF-β, expression throughout these time points (Fig. 2). Maximal expression was observed at 17 weeks by densitometric quantitation. Analysis of total RNA isolated from tissue of 32 to 34 weeks' gestation revealed minimal expression in 32 and 33 week samples with a striking increase of expression occurring at 34 weeks (Fig. 3).

We have looked at the expression of c-jun and jun-B in human placenta. These protooncogenes have been associated with cellular growth processes, including both proliferation and differentiation. Their patterns of expression did not correspond to that found with TGF- β_1 (unpublished data). This would imply that the

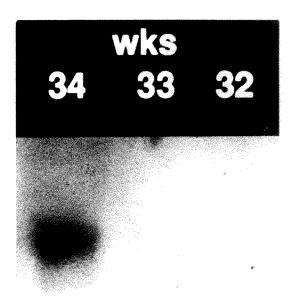

Fig. 3. Northern blot of total RNA samples of placental tissue in late gestation. Minimal expression occurred at 32 and 33 weeks with increased expression at 34 weeks.

increased expression of TGF-β₁ near 17 and 34 weeks' gestation is not related to a general phenomenon.

After identification of peak TGF-β, mRNA expression in 17 and 34 weeks' gestational age placental tissue, we used immunohistochemical analysis to localize TGF- β_1 protein expression in these tissues. TGF- β_1 protein expression was localized to the periphery of placental villi corresponding with the syncytiotrophoblastic layer (Fig. 4). There was an absence of staining of cell types of the villous core. Control specimens did not show this pattern of staining.

Fig. 4. Immunohistochemical analysis of 17-week placental tissue. TGF-β₁ protein expression is localized to syncytiotrophoblastic layer only. (Original magnification ×100.)

Comment

The placenta is a very dynamic organ, passing through stages of graft acceptance, cell differentiation, invasive growth, and cessation of both growth and invasiveness. Knowledge about regulatory factors involved in these processes is limited. TGF-β₁ promotes proliferation of some cell types but inhibits proliferation of others, depending on cell conditions and concentration. A fundamental property is its ability to inhibit proliferation of both normal and malignant cell lines.

The observations made in our study suggest that TGF-β₁ is expressed in human placenta throughout gestation. Additionally, two peaks of expression were noted: an initial peak occurring near midgestation at 17 weeks and a second peak in later gestation, near 34 weeks. In humans trophoblastic invasion of the myometrium is largely limited to the eighth through eighteenth weeks of gestation. Large numbers of cytotrophoblastic cells invade the decidua basalis and underlying myometrium. Fusion of cytotrophoblastic cells results in formation of syncytial cells. An absence of mitotic activity is noted in the syncytiotrophoblast. 12 Increased mRNA expression of TGF-β₁ near 17 weeks' gestation suggests that it may play a role in inhibition of myometrial trophoblastic invasion. Also, TGF-β₁ protein expression was localized to the syncytiotrophoblastic layer with immunohistochemical analysis.

The expression of TGF-β₁, a factor known to be related to inhibition of cell proliferation, in these mitotic endstage cells supports its possible role in the inhibition of cytotrophoblastic myometrial invasion. It is possible that different trophoblastic cell types may express TGF- β_1 near midgestation and be involved in myometrial invasion. Our studies, however, were able to identify only TGF-β, protein expression localized to the villous syncytiotrophoblast with an absence of staining of other cell types. Although we cannot rule out decidual contamination as a source of TGF-β₁ mRNA expression in our specimens, immunohistochemical analysis identified TGF-β, protein expression only in the syncytiotrophoblastic layer.

Absolute growth of human placenta as determined by deoxyribonucleic acid content declines in late gestation beginning at 35 to 36 weeks' gestation, at which time cytotrophoblastic proliferation essentially ceases.¹³ TGF-β₁ has been shown to inhibit rat trophoblastic cell deoxyribonucleic acid synthesis in a dose-dependent manner.¹⁴ A second peak of TGF-β₁ expression near 34 weeks' gestation may therefore be related to this cessation of cytotrophoblastic cell proliferation and decline in placental growth. This was again supported by localization of TGF-B1 protein expression in the syncytiotrophoblastic layer with immunohistochemical analysis.

In summary, with Northern blot analysis TGF-β,

expression was noted throughout gestation in our study. Peak expression was noted at 17 and 34 weeks' gestation. Immunohistochemical staining revealed TGF-β₁ expression restricted to the syncytiotrophoblastic layer. TGF-β₁ expression in the syncytiotrophoblast at these time points may be related to inhibition of cytotrophoblastic proliferation occurring at these stages of placental development. Pathologic conditions of trophoblastic invasion exhibited in gestational trophoblastic disease and choriocarcinoma represent a deviation from normal trophoblastic growth. We have not examined such tissues. Examination of these tissues with comparison to findings in nonpathologic conditions would be of value in further elucidation of the role of TGF-β₁ in regulating trophoblastic myometrial invasion.

Multicenter randomized clinical trial of home uterine activity monitoring for detection of preterm labor

Susan M. Mou, MD,^a Shirazali G. Sunderji, MD,^b Stanley Gall, MD,^c Helen How, MD,^c Vinu Patel, MD,^b Mark Gray, MD,^a Herbert L. Kayne, PhD,^d and Michael Corwin, MD^c

Kansas City, Missouri, Syracuse, New York, Chicago, Illinois, and Boston, Massachusetts

Home uterine activity monitoring has been described as an effective means of detecting uterine contractions, but controversy exists whether it is home uterine activity monitoring or increased nursing support in conjunction with it that contributes to earlier detection of preterm labor. In this study 377 women at risk for preterm labor from three centers were prospectively, randomly assigned to high-risk prenatal care alone (not monitored) or to the same care with twice-daily home uterine activity monitoring without increased nursing support (monitored). The two groups were medically and demographically similar at entry into the study. Routine visits, nonroutine visits, and gestational age at diagnosis of preterm labor were similar in both groups. Preterm labor occurred in 41 of 198 monitored and 39 of 179 not monitored patients. Mean cervical dilatation was 1.4 cm in 41 monitored compared with 2.5 cm for 37 not monitored ($\rho = 0.0006$); 73.1% of monitored and 27.5% of not monitored had preterm labor detected before 2 cm dilatation (p = 0.00009). Neonatal outcome of singleton pregnancies showed greater birth weight, fewer days in the neonatal intensive care unit, and fewer babies requiring oxygen therapy and mechanical ventilation in the monitored group. The better outcomes are probably due to the increased likelihood of diagnosis of preterm labor before advanced cervical dilatation with home uterine activity monitoring, thus providing the clinician with a better chance to initiate tocolytic therapy directed at improving pregnancy outcome. (AM J OBSTET GYNECOL 1991;165:858-66.)

Key words: Home uterine activity monitoring, preterm labor

Preterm delivery is the most significant contributor to perinatal morbidity and mortality in the United States.1 Unfortunately, many episodes of preterm labor are not detected until it is too late to provide effective tocolytic therapy. Recent studies have shown that an increase in the number of uterine contractions precedes the onset of preterm labor and is present in early labor; however, women often are not aware of the increased number of contractions until labor is advanced.2.3 Studies showing that devices designed to monitor uterine activity offer a more reliable method of quantitating contractions suggest that home uterine activity monitoring may allow earlier detection of the onset of preterm labor.4,5 Although many studies examining its efficacy have suggested beneficial effects, most of these studies have included intensive perinatal nursing support in combination with the objective data obtained with a device.⁵⁻⁷ Therefore it has not been possible to separate the effects of the detection of increased uterine activity. A prospective, randomized, blinded, multicenter trial of a home uterine activity monitoring device as the sole addition to current standard high-risk obstetric care was conducted to evaluate the effect of objective measurement of uterine activity in the diagnosis of preterm labor.

Methods

Recruitment and eligibility. Prenatal charts at three study sites, Truman Medical Center, Kansas City, Mo., State University of New York Health Science Center, Syracuse, N.Y., and the University of Illinois Hospital, Chicago, were reviewed at the time of the initial prenatal visit, at 22 to 26 weeks' gestation, and at 32 weeks' gestation. Recruitment was conducted from September 1988 to August 1989 at Truman Medical Center and the State University of New York, Syracuse, but was terminated in June 1989 at the University of Illinois because of intended closure of the hospital. Subjects were eligible for recruitment if they were found to have an increased risk of preterm labor as judged by a Creasy risk score of ≥10.8 Women were excluded if they had significant psychiatric problems precluding compliance with the study protocol, did not speak English, or were >32 weeks' gestation. Eligible patients were approached for informed consent and participation in the

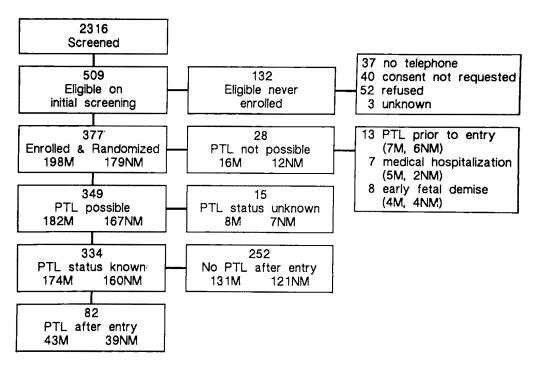

Fig. 1. Study population flow chart. M, Monitored; NM, not monitored; PTL, preterm labor.

study according to a protocol approved by institutional review boards at each study site. The 52 eligible women who refused randomization had Creasy risk scores similar to those of study participants. No other data are available on these women. The flow of patients from 2316 initially screened for eligibility through the 377 who were enrolled and randomized is shown in Fig. 1.

Randomization. All randomization and group assignment was performed by study personnel without direct patient care responsibilities. After enrollment, the group assignments were made by opening consecutively numbered envelopes that randomized patients by a table of random numbers. A different random number sequence was used for each study site, and each site had separate randomization sets for singletons and multiple gestations. No local study personnel had access to the group assignment.

On the basis of these procedures, the 377 patients were assigned to either the monitored group (n = 198) or the not monitored group (n = 179) (Fig. 1). The distribution of monitored and not monitored patients by site was as followed: Truman Medical Center had 82 monitored and 82 not monitored patients; State University of New York had 74 monitored and 68 not monitored patients; and University of Illinois had 42 monitored and 29 not monitored patients. The not monitored group received standard high-risk obstetric care, whereas the monitored group received the same standard high-risk obstetric care plus twice daily home uterine activity monitoring.

Obstetric care

Education. All patients, regardless of group assignment, received education regarding why they were at risk for preterm labor and information about preterm labor precautions, including these signs and symptoms of preterm labor: (1) uterine contractions, (2) dull, low backache, (3) menstrual-like cramps, (4) diarrhea or indigestion, (5) pressure or heaviness in the lower abdomen, back, pelvis, or thighs, (6) vaginal discharge, and (7) vaginal drainage or leaking of amniotic fluid. They were also instructed to notify their physician or clinic if they suspected preterm labor. All patients received education about the monitoring protocol (see below) and uterine self-palpation.

Monitoring protocol. The home uterine activity monitoring device used for this study was the Genesis System (Physiologic Diagnostic Service, Atlanta). The system consists of a guard ring type tocodynamometer connected to a portable battery-operated data recorder, a communication module allowing transmission of data over standard telephone lines, and a receiving computer with strip chart.

Patients in the monitored group received instruction on use of the Genesis System at 24 to 26 weeks or at time of entry into the study if they were enrolled at 26 to 32 weeks. Patients were to monitor for 1 hour twice daily, 7 days per weeks. Monitoring began at 24 weeks and continued to 37 weeks or delivery, if delivery occurred at <37 weeks. If patients entered the study after 24 weeks' gestation, they began monitoring on enroll860 Mou et al.

ment. The patients were scheduled for twice-daily (in the morning and evening) uterine activity data transmission. No advice or instructions were given over the telephone. In addition, patients were instructed to use the system for 1 hour if they experienced any signs or symptoms of preterm labor. These unscheduled sessions were transmitted immediately. All monitoring was performed in the patient's home, and the uterine activity data were transmitted by telephone to a remote site. The receiver personnel served to facilitate the transmission of the uterine contraction data and report the number of contractions to the patient. Patients were previously informed that the personnel would not be able to answer questions, and the personnel were instructed to neither ask medical questions nor give medical advice. The investigators verified on an ongoing basis that the personnel provided no medical information to the monitored patients.

Procedures for routine and nonroutine visits. For both routine and nonroutine care, women in both groups were seen by obstetric caretakers as part of the usual high-risk obstetric care provided at their respective perinatal sites. The minimum care scheduled was a visit every 4 weeks until 30 weeks' gestation, at least every 2 weeks between 30 and 36 weeks, and at least weekly thereafter. The actual schedule was based on each patient's medical problems, and, in general, subjects had more scheduled routine visits than the minimum required.

Nonroutine visits were indicated if the patient had signs or symptoms of preterm labor as described above. Nonroutine visits were obtained at the obstetric care provider's office or clinic during the day, and in hospital labor and delivery units, at night. The indications and procedures followed for nonroutine visits were the same for the two groups. In the case of suspected uterine contractions, the action to be taken by the patient was the same if the monitoring data showed increased contractions or if the patient had the sensation of increased contractions. It consisted of the following: (1) If, on the basis of patient sensation or monitoring, there were four or more contractions per hour lasting >40 seconds, the patient was to assume a left recumbent position, take oral hydration, empty the bladder, and then reassess the number of contractions for 1 hour. (2) If on reassessment there were four or more contractions per hour, then a nonroutine medical visit was indicated. (3) For twin gestations, six contractions per hour rather than four were used in this protocol. This was based on data showing higher baseline contraction frequencies at each week of gestation from 23 to 36 weeks in twin gestations as compared with singleton gestations.5,9 All patients were allowed to arrange a

nonroutine visit for prompt evaluation if they felt it was necessary.

When patients were seen with possible preterm labor, fetal monitoring and cervical examinations were performed by experienced examiners (senior residents or attending physicians) who were not aware of the subject's group assignment. Preterm labor was defined, before the beginning of the study, as four or more contractions per hour plus a change in cervical examination, or four or more contractions per hour and a cervical examination showing >2 cm dilatation and 75% effacement and/or ruptured membranes. In actuality, patients who were diagnosed with preterm labor all had a cervical change of effacement or dilatation as compared with their most recent cervical examination. Tocolytic therapy was prescribed at each of the study sites according to previously existing protocols. In general, treatment at all sites for established preterm labor included bed rest, hydration, evaluation for acute medical problems, and, if no contraindications for drug treatment existed, infusion of one of the common intravenous tocolytics (ritodrine hydrochloride, magnesium sulfate, or terbutaline). If labor stopped, this intravenous therapy was followed by oral tocolytic therapy.

Blinding. All patients were instructed not to inform caretakers of group assignment. Caretakers were informed that they were seeing a study patient but not told the group assignment. If uterine contractions were suspected, caretakers were not informed if the contractions were detected by the monitor or the patient. If a potential examiner inadvertently learned a patient's group assignment, then the study cervical examination was performed by a different experienced caretaker who was not aware of the group assignment.

Statistics

Sample size. As part of planning this study, the sample size calculation was performed on the basis of cervical dilatation of <2 cm being the definition of early detection of preterm labor and assuming that 60% of monitored patients would have early detection compared with only 30% of not monitored patients. Alpha was 0.05 and β was 0.20 (power = 80%). Thus 48 patients with preterm labor per group would be required. It was further assumed that 30% of the enrolled highrisk patients would have preterm labor so that a total enrollment of 320 would be required.

Statistical analysis. Two group comparisons were made with t tests or Wilcoxon rank sum tests, depending on frequency distributions for continuous variables. χ^2 tests or Fisher's exact probabilities (depending on number of categories and cell counts) were done for categorical variables. Three group comparisons were made

Results

Comparison of groups at entry. The demographic and medical characteristics of the monitored and not monitored groups are summarized in Table I. At entry to the study no significant differences were observed between the two groups for any of these characteristics. This was true for both the 377 patients originally randomized and the subgroup of 82 who went on to have preterm labor. In addition, since randomization was stratified by site and twins, it was verified that within each randomization no significant differences were observed between the monitored and not monitored groups in any of their medical and demographic characteristics.

Comparison of groups after entry. Several analyses were performed to verify that the two groups received similar care after entry to the study. There were no significant differences between the two groups. The number of routine visits per patient among the monitored and the not monitored patients was 7.1 and 6.7, respectively. For nonroutine visits the monitored patients averaged 2.0 visits and not monitored patients averaged 1.8 visits. Fig. 2 illustrates the number of routine and nonroutine visits for the two groups during each week of gestation that the patients participated in the study.

The incidence and timing of preterm labor was also similar for the two groups. Preterm labor was detected in 43 of 174 (24.7%) monitored patients and in 39 of 160 (24.4%) not monitored patients (Fig. 1). The average gestational age at diagnosis of preterm labor was 32.9 weeks for both groups (Table II).

Cervical dilatation at diagnosis of preterm labor. The primary end point for the study was the timing of detection of preterm labor as measured by the cervical dilatation at the time of diagnosis. Cervical dilatation data were available for 77 of the 82 subjects who had preterm labor. Dilatation data were not recorded at the time of diagnosis of preterm labor for two monitored and two not monitored subjects. Dilatation data for one not monitored subject were not used because a cerclage was in place at the time of the diagnosis of preterm labor.

Women in the monitored group had significantly less cervical dilatation at the time of diagnosis of preterm labor (Table II). The mean dilatation for the monitored group was 1.4 cm compared with 2.5 cm in the not monitored patients (p = 0.0006). Some patients had cervical dilatation before the onset of preterm labor; therefore the change in dilatation from the cervical examination immediately prior to the onset of preterm labor also was studied. Women in the monitored group had a mean change in cervical dilatation of 1.1 cm

compared with 2.0 cm in not monitored women (p = 0.004).

In addition to evaluating the overall distribution of cervical dilatation, the likelihood of early detection of preterm labor was also determined. The initial sample size calculation for the end point of cervical dilatation was based on the definition of early detection of preterm labor being a cervical dilatation of <2 cm, and it was assumed that 60% of monitored patients would have early detection compared with only 30% of not monitored patients. Detection of preterm labor before

2 cm cervical dilatation was actually accomplished in 73:1% of monitored subjects compared with only 27.8% of not monitored subjects (p=0.00009) (Fig. 3, B). Since clinicians may vary with regard to their definition of early detection of preterm labor, Fig. 3 shows the group comparisons with four different cutoff values (1, 2, 3, and 4 cm) for early detection. The monitored group had significantly earlier detection than the not monitored group for all four cutoff values.

Since patients with preterm labor represent a subset of the original randomized groups, multiple regression

^{*}Medically indicated preterm deliveries (one in each group) were excluded from these analyses.

analysis was performed with dilatation at diagnosis of preterm labor as the dependent variable and numerous independent variables, such as obstetric history variables including substance use, study site, and monitoring versus not monitoring. The only variable that had a significant independent effect on dilatation at diagnosis was use of the monitor, which was associated with a 0.9 cm decrease in cervical dilatation (p = 0.01). Cohort analyses were done for women who entered the study at <25 weeks' gestation, at ≥27 weeks, and at ≥29 weeks' gestation. Mean cervical dilatation and cervical change at the diagnosis of preterm labor was less in the monitored group for all of these cohorts.

Pregnancy and neonatal outcome. To evaluate the clinical importance of the early detection of preterm labor observed in the monitored group, duration of gestation after diagnosis of preterm labor (Table II), infant birth weight, and measures of neonatal morbidity (Table III) were compared between the two groups.

The mean duration of gestation after diagnosis of preterm labor was 3.7 weeks in 41 monitored patients (one patient did not have gestational age at delivery recorded and one was excluded because of medically indicated preterm delivery) compared with only 2.0 weeks in 38 not monitored patients (one excluded because of medically indicated preterm delivery [p = 0.02]) (Table III). Therefore the mean gestational age at delivery was 36.6 weeks in the monitored group compared with only 34.9 in the not monitored group (p = 0.009) (Table II). These gestational duration data do not significantly change if the two medically indicated preterm deliveries are included in the analysis. Multiple regression analysis also was performed with gestational age at delivery as the dependent variable and numerous independent variables including age, race, Creasy score, substance use variables, maternal

^{*}Dilatation data were not available for two monitored and three not monitored subjects.

[†]Gestational age at delivery was not available for two monitored and one not monitored subjects.

[†]Birth weight data were not available for two monitored infants who were born at term.

history variables, study site, monitoring versus not monitoring, and cervical dilatation at diagnosis of preterm labor. The only variable that had a significant independent effect on gestational age at delivery was cervical dilatation at diagnosis of preterm labor, which was associated with a 0.6-week decrease in gestational age at delivery for each centimeter increase in dilatation (p = 0.03).

Birth weight and neonatal morbidity variables were evaluated after exclusion of 17 (nine monitored and eight not monitored) twin gestations and two (one in each group) medically indicated preterm deliveries. In addition, there were two patients for whom birth weight data were not available. Twin gestations were excluded from these analyses because of the potential effects of twinning on birth weight and neonatal morbidity.

Birth weight of singletons differed significantly between the monitored and not monitored groups. The mean birth weight of infants from the monitored group (n = 31) was 2934 gm compared with only 2329 gm for the not monitored group (n = 30) (p = 0.002). Only 19% of infants from the monitored group weighed <2500 gm versus 63% of the not monitored babies (p = 0.0007). The incidence of infants weighing <2000 gm was only 10% for the monitored group compared with 37% for the not monitored group (p = 0.02) (Table III). Singleton infants born to monitored women also suffered significantly less neonatal morbidity as measured by need for neonatal intensive care, oxygen therapy, and mechanical ventilation (Table III). Only five infants (50 total neonatal intensive care unit days) of the 33 monitored singleton gestations required admission to the neonatal intensive care unit (p = 0.02). None of the 33 infants who were products of monitored singleton gestations required oxygen therapy or mechanical ventilation compared with seven infants who required oxygen therapy, for a total of 68 days (p = 0.004), and five infants who required mechanical ventilation for a total of 54 days (p = 0.02) among the 30 products of not monitored singleton gestations (Table III).

There were 252 patients who were randomized into monitored and not monitored groups who did not experience preterm labor outcome. Data were available on 250 patients. The mean gestational age at delivery of the controls without preterm labor was 39.1 weeks (± 2.3 weeks SD). The mean gestational age at delivery of the monitored group without preterm labor was 38.8 weeks (± 2.1 weeks SD), p=0.28. Likewise, the birth weights of the singletons in the control group without preterm labor was 3154 gm (\pm 654 gm SD) and the birth weights of singletons in the monitored group was 3269 gm (\pm 604 gm SD), p=0.18.

Comment

This study demonstrates that objective assessment of uterine activity, by home uterine activity monitoring in women at high risk for preterm labor, allows detection of preterm labor at less advanced cervical dilatation. The clinical importance of this earlier detection of preterm labor is supported by the increased gestational duration after diagnosis of preterm labor and the resultant improved gestational age at delivery, increased birth weight, and decreased neonatal morbidity observed in the monitored group.

This report represents the largest published, prospective, multicenter, randomized, and blinded evaluation of the efficacy of home uterine activity monitoring for earlier detection of preterm labor in high-risk pregnancies. Previously published studies have suggested beneficial effects of home uterine activity monitoring^{3, 5, 6}; however, the study designs used did not allow for the separation of the impact of the use of the monitor from the impact of the additional perinatal nursing support.7, 10 Some studies3, 6 did not provide comparison groups receiving the same perinatal center obstetric care. The studies that failed to show beneficial effects of home uterine activity monitoring have not focused on the value of the device when it is used without additional nursing care.11.12 Also, the present study differs from others in using twice-daily monitoring and transmission of data, rather than once-daily transmission of monitor strips:

When one is evaluating a new device, it is essential to separate clearly those effects that are a result of the information derived from the use of the device from those effects of other nonstandard interventions. Previous studies have evaluated daily perinatal nursing support used along with home uterine activity monitoring. The current report evaluates the impact of the addition of objective assessment of uterine activity to high-risk obstetric care on pregnancy outcome. In this study design, (1) no routine daily perinatal nursing support was provided to either group, (2) all study patients were provided with identical high-risk obstetric care and education in self-palpation of uterine contractions (as described by Herron et al.18), (3) caretakers were blinded to subject's group assignment, (4) preterm labor was strictly defined, (5) all subjects were included in the data analysis on the basis of their original group assignment regardless of compliance, and (6) the primary end point was cervical dilatation at diagnosis of preterm labor, since other variables (e.g., incidence of preterm birth) are strongly related to the incidence of preterm labor in the study population and to the effectiveness of tocolytic therapy.

Although caretakers were blinded to the subjects' group assignments, it is not possible to be absolutely certain that all examiners were indeed unaware of a patient's group assignment. It is estimated that not more than six women were examined by caretakers who were aware of the patient's group assignment. The results of the study did not change when these patients were excluded from the data analysis.

The study did not include a sham monitoring group, and therefore it is not possible to determine the independent effects of the four procedures that are an integral part of the monitoring protocol. These procedures, which represent the only known differences between the two groups, include (1) wearing a tocodynamometry belt during each recording session, (2) relative inactivity during each recording session, (3) data transmission after each recording session, and (4) patient notification if four or more contractions were observed. Although it is possible that any of these four procedures may have contributed to the results, detection and notification of increased contractions is the most reasonable explanation for the early detection of preterm labor observed in the monitored group. There were similar outcomes in the control and monitored group among patients who did not go into preterm labor, which also makes the twice daily monitoring unlikely to affect the course of the pregnancies except for diagnosing preterm labor at an earlier cervical dilatation.

The benefit of monitoring appears to be in the earlier detection of preterm labor, before perception by the patient and before significant cervical dilatation has occurred. Self-palpation of uterine contractions had been shown to be less sensitive than tocodynamometry in detecting uterine activity.2, 14 Objective quantitation of contractions is a useful method of surveillance for preterm labor and detects contractions before women perceive them.2 Since progression of labor occurs over hours rather than days or weeks one would not expect the gestational age at diagnosis of preterm labor to differ significantly between the groups as shown in this study, with mean gestational age at diagnosis of preterm labor at 32.9 weeks in the monitored and not monitored groups. The observation that there were no differences between the groups for the gestational age at the time of diagnosis of preterm labor and the incidence of preterm labor makes it unlikely that overdiagnosis of preterm labor or lead time bias could account for the results of the study. This protocol did not address specific tocolytic regimens. Once preterm labor was diagnosed, each center continued its usual protocols. Therefore it is not possible to assess the relative effects of various medical interventions on the outcomes. The fact that the vast majority of caretakers were unaware of the patient's group assignment makes it unlikely that there were significant differences between the medical interventions received by the two groups. In addition, the two groups were medically and demographically similar at entry into the study and at the time of diagnosis of preterm labor. They had similar numbers of routine and nonroutine obstetric visits, incidence of preterm labor, similar gestational age at diagnosis of preterm labor, and were similar in the relationship between dilatation at diagnosis of preterm labor and subsequent duration of gestation.

Zlatnik¹⁵ and King et al. ¹⁶ have shown that long-term tocolysis with significant prolongation of gestation is possible if preterm labor is diagnosed before advanced cervical dilatation. Multiple regression analysis confirmed that earlier detection of preterm labor in the monitored group led to significant prolongation of gestation. Although there is disagreement as to the specific definition of advanced cervical dilatation, a significantly higher percentage of the monitored patients in this study had early detection of preterm labor, as measured by cervical dilatation, whether <1, 2, 3, or 4 cm dilatation was used as the cutoff for early detection. The result was improved gestational age at delivery and increased birth weight of infants in the monitored group.

A medically and sociodemographically diverse population from three perinatal sites participated in this study. Subgroup analyses were performed with specific medical risk factors, gestational ages at entry, gestational ages at diagnosis of preterm labor, and compliance with study protocol. The results of these analyses showed that the information derived from home uterine activity monitoring appeared to be similarly beneficial for all patients who used the monitor. The subset of the monitored group (n = 12) who did not comply with the protocol had results that were similar to those of the not monitored group. Prior preterm delivery was the only medical risk factor for preterm labor for which there were a sufficient number of patients for separate analysis. These data were consistent with the data for the entire study population showing beneficial effects for all outcome variables. On the basis of these study data, the United States Food and Drug Administration has given approval for use of this device in women with a history of preterm birth.17 Although none of the other individual medical risk factors had a sufficient sample size for separate analyses, when considered as one group (containing the 31 patients without a history of preterm birth), the monitored group showed significant beneficial effects similar in magnitude to the subset of women with a history of preterm birth. Women with other medical risk factors for preterm labor may therefore also benefit from home uterine activity monitoring. Future studies may further address the benefit in women with other specific maternal risk factors.

Our study demonstrates that home uterine activity monitoring, when used in selected high-risk women as the sole addition to standard high-risk care, results in earlier detection of preterm labor. This led to an impressive mean 1.7-week improvement in gestation compared with not monitored women, as well as a mean 605 gm greater birth weight.

In summary, this study demonstrated that use of home uterine activity monitoring, in selected high-risk patients, significantly increases the likelihood of diagnosis of preterm labor before advanced cervical dilatation, thus providing the clinician with a better opportunity to initiate tocolytic therapy directed at improving pregnancy outcome.

We are indebted to David Simic, Anita Quinlan, Christine Falchi, and Laurie Dressman for their role in coordinating the data collection and to Dr. Howard Golub for his help in the statistical analyses.

Adjunctive clindamycin therapy for preterm labor: Results of a double-blind, placebo-controlled trial

James A. McGregor, MDCM, Janice I. French, CNM, MS, and Kyung Seo, MD, PhD Denver, Colorado

A double-blind, placebo-controlled, randomized trial was conducted to evaluate the efficacy, safety, and tolerance of a course of clindamycin (administered for 3 days intravenously and 4 days orally) among hospitalized women with preterm labor at ≤34 weeks' gestation who were treated with tocolytics. One hundred three woman-perinate pairs were analyzed. Univariate analysis demonstrated that pregnancies were continued longer in women treated with clindamycin than in women who received placebo (clindamycin-treated group, 35 days; placebo-treated group, 25 days; p = 0.02). Survival analysis showed that pregnancy continued at least 35.5 days in 50% of clindamycin-treated women versus 20 days for control women (p = 0.03). Obstetric and microbiologic parameters associated with treatment outcomes were also sought. Women with bacterial vaginosis more often delivered preterm (p = 0.03; relative risk, 1.4; 95% confidence interval, 1.04 to 2.0). Among women with bacterial vaginosis, trends for increased duration of pregnancy (clindamycin-treated group, 36 days; placebo-treated group, 19 days), increased birth weight (clindamycin-treated group, 2634 gm; placebo-treated group, 2256 gm), and increased mean gestational age at delivery (clindamycin-treated group, 35 weeks; placebo-treated group, 34 weeks) were associated with clindamycin treatment. Women with either group B streptococcus, Chlamydia trachomatis, Trichomonas vaginalis, or Staphylococcus aureus were more likely to have preterm premature rupture of membranes (p = 0.01). Clindamycin treatment of these women reduced the incidence of preterm premature rupture of membranes to that of uninfected subjects. Stratification by gestational age at enrollment showed clindamycin treatment to be associated with an increased interval to delivery only among mothers enrolled before 33 weeks' gestation (clindamycin-treated group, 40 days; placebo-treated group, 28 days; p < 0.05). Treatment with clindamycin appeared safe and well tolerated, with benefits limited to women who were ≤32 weeks' gestation. (Am J OBSTET GYNECOL 1991;165:867-75.)

Key words: Preterm labor, antibiotics, infection, bacterial vaginosis

Preterm birth remains a leading cause of infant morbidity and mortality. In spite of much effort to identify and provide intensive antenatal surveillance to women at risk, the occurrence of preterm birth in the United States appears to have increased between 1985 and 1987.1 Considerable information suggests that maternal reproductive tract infection and associated inflammation may play initiating or contributory roles in the pathogenesis of preterm labor and birth for significant numbers of pregnant women.2 Effective antibiotic treatment of undetected maternal reproductive tract infection may allow for prolongation of pregnancy and may improve outcome for women with preterm labor. Previous trials of antimicrobial therapy in addition to tocolytic therapy for women in preterm labor have yielded encouraging but inconsistent results.3-6 Differ-

ences in study design, populations, and/or prevalence of reproductive tract infections and antibiotic selection may contribute to such differences.

In this study we evaluated use of clindamycin as adjunctive antimicrobial treatment for women hospitalized with idiopathic preterm labor to evaluate possible pathogenic roles for reproductive tract infection in preterm birth and to identify women most likely to benefit from such antimicrobial treatment.

Material and methods

Between July 1986 and April 1989, women who were hospitalized at ≤34 weeks' gestation and who received parenteral tocolytic agents for idiopathic preterm labor were asked to participate in this double-blind, placebocontrolled trial. Each participant completed an informed consent form approved by the human subjects committee of the University of Colorado Health Sciences Center or the Denver Department of Health and Hospitals.

Patients were excluded from the study for the following reasons: (1) the presence of a recognized cause of preterm labor or obstetric complication, such as placenta previa, multiple gestation, abruptio placentae, cervical cerclage, known uterine or fetal anomaly, pregnancy-induced hypertension, or premature rupture of membranes; (2) known or suspected infection necessitating treatment, e.g., clinically recognized chorioamnionitis, urinary tract infection, or pneumonia; (3) fetal indication for delivery; (4) clinically significant maternal cardiac, respiratory, liver, renal, or immunologic disease; (5) use of antibiotics within 2 weeks before the start of the study; (6) a history of diarrhea or colitis; (7) sensitivity or intolerance to clindamycin.

On enrollment, medical, obstetric, and behavioral information was recorded. A clean-voided urine sample was collected for urinalysis and culture. A blood sample for complete blood count with differential count was obtained. An examination was performed with a sterile vaginal speculum; separate endocervical samples were immediately inoculated onto a chocolate agar and a modified Thayer-Martin split plane for recovery of Neisseria gonorrhoeae and into sucrose-phosphate glutamate transport media for recovery of Chlamydia trachomatis. Samples from the cervix and upper vagina were inoculated onto 5% sheep blood agar (tryptic soy base, Remel, Denver) for recovery of group A streptococcus, group B streptococcus, Staphylococcus aureus, Gardnerella vaginalis, and yeast species. Additional lateral vaginal wall samples were inoculated in standard mycoplasma medium for recovery of Mycoplasma hominis and Ureaplasma urealyticum and were placed in 1 ml of saline solution for microscopic examination for motile trichomonads and yeast pseudohyphae. Release of amine odor ("whiff test") from a sample of vaginal fluid was tested by the addition of 10% potassium hydroxide. Another sample of vaginal fluid was allowed to air dry on a slide for Gram's stain evaluation for bacterial vaginosis and Mobiluncus sp. bacterial morphotypes.7 Microbiologic cultures were processed and microorganisms were identified by means of standard techniques.8,9

After laboratory specimens were obtained, women in the study were randomly assigned according to a computer-generated random number list to receive either intravenous clindamycin 900 mg every 8 hours for nine doses or a similarly packaged and labeled saline solution placebo. Intravenous therapy was followed by treatment with oral clindamycin 300 mg four times daily for 4 days or with an identical-appearing lactose placebo to complete 1 week of therapy. Intravenous study treatment was prepared and double blinded by the hospital pharmacy. Corresponding oral study treatment was prepared and double blinded by The Upjohn Company, Kalamazoo. Women discharged from the hospital before completion of oral treatment were given the study bottle and a medication diary in which to record medications taken at home. Undelivered subjects were seen in the antenatal clinic by one of the investigators 2 to 4 weeks after the completion of study treatment.

At this time medication bottles and diaries were collected. Women were questioned regarding side effects, and all initial microbiologic sampling was repeated. Participants continued their care in a specialized obstetric clinic. Follow-up information was obtained by review of maternal and newborn records through 6 weeks post partum and 3 months of life, respectively.

All participants received parenteral tocolytic therapy (subcutaneous or intravenous terbutaline, intravenous magnesium sulfate, or intravenous ritodrine, or a combination of these medications). Tocolytic therapy and study treatment were discontinued if labor persisted and delivery was considered clinically inevitable or if evidence of maternal intolerance, fetal distress, or preterm rupture of membranes occurred. Successful tocolysis was followed by oral tocolytic therapy with either terbutaline or nifedipine until 37 weeks' gestation was achieved or until findings of recurrent labor necessitating parenteral treatment were noted. Subsequent episodes of preterm labor were treated according to obstetric protocols without further study therapy. Amniocentesis was not specifically performed as part of this protocol. Betamethasone (12.5 mg each 24 hours for two doses, intramuscularly) was administered to the mother if clinically indicated. Obstetric care providers were informed if subjects were colonized with group B streptococcus; neonatal care providers were informed when C. trachomatis or group B streptococcus was recovered. Women in whom group B streptococcus was identified were given intravenous ampicillin when active labor began or when membranes ruptured.

Gestational age at enrollment was determined by a combination of "best" overall obstetric criteria,10 including last menstrual period, detection of fetal heart rate with fetoscope, fundal height measurements, and ultrasonographic measurements. After delivery, overall gestational age was determined by combining those criteria with newborn examination.11 Preterm labor was defined as two or more uterine contractions in 20 minutes that persisted after bed rest and intravenous hydration and required administration of parenteral tocolytic therapy because of change in cervical dilatation or effacement. Birth at <37 completed weeks' gestation was considered preterm. Premature rupture of membranes was defined as rupture of membranes that occurred after successful tocolysis and >1 hour before the onset of uterine contractions leading to birth. Chorioamnionitis was based on clinical criteria that included maternal intrapartum fever ≥38° C and two or more of the following: maternal tachycardia, fetal tachycardia, maternal leukocytosis, or uterine tenderness. Diagnosis of postpartum endometritis was determined by findings of fever, uterine tenderness, and foul or purulent lochia.

Before study initiation, it was determined that a sam-

ple containing 57 patients in each group would detect a 25% increase in the number of women achieving 37 weeks' gestation with a power of 80% and at the 0.05 significance level. This was based on the assumption that 50% of women receiving tocolytic therapy are delivered at term. 12 Clindamycin was selected as the study agent principally because of its relatively focused antimicrobial activity against several microorganisms implicated in preterm birth (group B streptococcus, genital mycoplasmas, C. trachomatis, and aerobic and anaerobic microflora associated with bacterial vaginosis) and because of the relative ease and safety of both intravenous and oral administration. In a previous trial3 we demonstrated that oral administration of erythromycin was associated with prolongation of pregnancy only among women with cervical dilatation ≥1 but ≤4 cm; several women were intolerant of oral erythromycin treatment. A review of antibiotic-associated diarrhea and pseudomembranous enterocolitis at the study sites showed that clindamycin use was not associated with increased occurrence of diarrhea in comparison with other antibiotics. Clindamycin use among newborns of varying gestational ages is well described.13

Data were summarized with descriptive statistics. Treatment group differences for categoric variables were evaluated by means of χ^2 tests, and normally distributed, continuous data were evaluated with twotailed Student's t test. Nonparametric or skewed data were evaluated with Wilcoxon's rank sum test. Survival analysis (SAS LIFETEST Procedure; SAS, Cary, N.C.) was performed to compare treatment group differences for time gained from study entry to delivery. The effect of treatment on microbiologic findings was evaluated with McNemar's χ^2 test for paired data. To control for potentially confounding effects of treatment and microorganisms, data were stratified according to presence of bacterial vaginosis and other susceptible microorganisms. Multiple regression analysis was performed to control effects of possible confounding variables in the prediction of days from study entry to delivery. Finally, logistic regression was performed with BMDP Statistical Software (Los Angeles) to control for the effects of potentially confounding variables on the outcome variable preterm birth.

Results

One hundred seventeen women were enrolled in this study. Fourteen subjects were excluded from analysis before the unblinding of the treatment code and data analysis. Fetal distress developed in one patient who underwent an emergent cesarean delivery before she received study treatment. Two patients withdrew consent, one before study treatment and one after an apparent allergic reaction to the initial dose. Three patients were withdrawn from the study when clinical

chorioamnionitis was detected; each had received a single dose of study treatment. One patient was delivered of previously undetected twins. Six subjects who were enrolled in spite of having exclusion criteria were eliminated from analysis. A final patient was excluded as a result of pharmacy error. All other patients were evaluated regardless of the number of doses they received. The total sample evaluated included 103 women and their newborns; 53 received clindamycin and 50 patients received placebo.

During study drug treatment, a single patient received ampicillin for group B streptococcus prophylaxis as a result of refractory labor, and another received ampicillin because of preterm rupture of membranes; each patient had received placebo. None of the four clindamycin-treated women in whom group B streptococcus was identified received additional antibiotics during study treatment. Ampicillin was given to those women when active labor began (10 to 59 days) after enrollment or if they had premature rupture of membranes. One patient in each study group received oral amoxicillin because of bronchitis or otitis media during study treatment; another patient who received placebo also was treated with oral metronidazole for G. vaginalis bacteriuria. The two remaining women with bacteriuria at study enrollment received nitrofurantoin. Each of these patients who received a nonstudy antibiotic was included in the analysis.

There were no differences among the multiple demographic, obstetric, or behavioral parameters for women who received clindamycin or placebo (all data not shown; Table I). Mean gestational age at enrollment did not differ between treatment groups. Thirty-nine clindamycin patients (73.6%) and 32 placebo patients (64.0%) were ≤32 weeks' gestation at enrollment. There were no differences for mean Bishop's scores at enrollment, duration of parenteral tocolysis, or types of tocolytic used for clindamycin- and placebo-treated women. Ninety-eight percent of both treatment groups received terbutaline; 66% of clindamycin-treated subjects and 58% of women given placebo received magnesium sulfate. Fewer women in each treatment group were given ritodrine (four clindamycin, three placebo) or nifedipine (three clindamycin, six placebo) for tocolysis. All subjects received parenteral tocolytic therapy for at least 24 hours unless delivery occurred within the first study day. The majority of subjects were multiparous. Among multigravid clindamycin-treated women, 62.2% had experienced a prior preterm birth, compared with 44% of multigravid women randomized to placebo (p = 0.2).

Thirty-eight percent of clindamycin-treated women and 42% of placebo-treated women experienced lesser medical problems during their antenatal care before study enrollment. Medical conditions were well con-

trolled and included asthma (two patients), gestational diabetes (seven patients), hypothyroidism (one patient), pyelonephritis (one patient), anemia (22 patients), and seizure disorder (two patients). In addition, three women were monitored for intrauterine growth retardation and two for isoimmunization. Two women had experienced hyperemesis gravidarum.

Maternal microbiologic findings are shown in Table II. There were no study group differences for any of the microorganisms recovered at enrollment. Two to 4 weeks after the completion of study treatment, 31 clindamycin subjects (58.5%) and 26 placebo patients (52.0%) were reexamined for microbiologic findings. Clindamycin treatment was associated with significant reduction in recovery of *M. hominis* and with the identification of bacterial vaginosis. The number of women in whom *G. trachomatis, Mobiluncus* sp. bacterial morphotypes, *S. aureus*, and group B streptococcus were identified was too small to allow for evaluation of treatment effects. Recovery of yeast species was not increased after clindamycin treatment (Table II).

Amniotic fluid was obtained from 31 clindamycin patients (58.5%) and 24 placebo patients (48.0%). Thirty-nine percent of clindamycin patients and 46% of placebo patients had polymorphonuclear leukocytes noted on Gram's stain evaluation of amniotic fluid samples. One amniotic fluid culture was positive in each

group (clindamycin-treated group, nonhemolytic streptococcus; placebo-treated group, Fusobacterium necrophorum).

Overall, preterm birth (<37 weeks' gestation) occurred among 62% of the enrolled women. Univariate analysis showed that pregnancies continued significantly longer in clindamycin-treated women than in those receiving placebo (clindamycin-treated group, mean 35.3 days and range 0 to 115; placebo-treated group, mean 25.4 days and range 1 to 77; p=0.02; Table III). Survival analysis demonstrated that pregnancies continued at least 35.5 days in 50% of women treated with clindamycin but 50% of placebo patients had been delivered by 20 days (p=0.03) (Fig. 1).

When gestational age at enrollment was controlled by stratification (\leq 32 and 33 to 34 weeks' gestation), univariate analysis showed that clindamycin treatment was associated with a prolonged mean interval from study entry to delivery only among women enrolled before 33 weeks' gestation (enrolled \leq 32 weeks; clindamycin-treated group, 40.4 days; placebo-treated group, 29.0 days; p < 0.05; enrolled 33 to 34 weeks: clindamycin-treated group, 21.0 days; placebo-treated group, 18.9 days, p = 0.7).

Stepwise multiple regression analysis with backward elimination was performed; independent variables included study treatment, bacterial vaginosis, gestational

NS, Not significant.

age at enrollment, cervical dilatation, and cervical effacement (Table IV). Increased cervical dilatation (p < 0.0001) and effacement (p = 0.09) at enrollment and gestational age at enrollment (p < 0.008) were associated with reduced time from enrollment to delivery. It is important to note that prolongation of pregnancy associated with clindamycin treatment persisted after controlling for the effects of cervical dilatation, effacement, and gestational age at enrollment. The presence of bacterial vaginosis, C. trachomatis, group B streptococcus, T. vaginalis, or S. aureus was not significantly related to number of days gained from study entry to delivery when multivariate analysis was used.

Newborns of mothers treated with clindamycin re-

quired a mean of 7.1 days of level II or III nursing care versus 16.8 days for those whose mothers received placebo (NS) (Table III). There were no statistically significant differences for birth weight (mean weight: clindamycin-treated group, 2586 gm; placebo-treated group, 2441 gm), gestational age at birth, number of women delivered before 37 or ≤32 weeks' gestation, the number of low-birth-weight infants, the number of readmissions because of episodes of acute premature labor, or any other neonatal outcome evaluated (Table III).

Other outcomes (Table III) of clinical interest were not different but require explanation. In addition to the three women who were diagnosed with clinical cho-

^{*}Recovery or identification rates were not different, except as noted.

rioamnionitis after a single dose of study treatment and who were excluded from analysis, clinical chorioamnionitis later developed in one clindamycin patient and three placebo patients. Four women in each treatment group were treated for postpartum endometritis. Two newborns (one from each group) were treated for bacteremia and four were treated for pneumonitis. Two neonatal deaths occurred, each of the mothers of these infants had received clindamycin. One infant who died was born at 25 weeks' gestation and weighed 815 gm; the other was 27 weeks' gestation at birth and weighed 940 gm. Both deaths were attributed to complications of prematurity. Two additional infant deaths were attributed to sudden infant death syndrome; one from the clindamycin group occurred at age 31/2 months inan infant born at 35 weeks' gestation, and one from the placebo group occurred at age 7 months in an infant born at 32 weeks' gestation.

To further explore the role of microorganisms in preterm birth, we compared women with and without specific microorganisms or conditions and controlled for study treatment. Overall, 25% of enrolled women had bacterial vaginosis; 20 of these 25 women (80%) were delivered preterm. In comparison, 41 of 74 women (55.4%) without bacterial vaginosis were delivered preterm (p = 0.03; relative risk, 1.4; 95% confidence interval, 1.04 to 2.0). Logistic regression analysis confirmed that bacterial vaginosis was the only microbiologic independent variable that predicted preterm birth (p < 0.05; odds ratio, 3.2; 95%, confidence interval 1.1 to 9.6). Clindamycin treatment in women with bacterial vaginosis showed trends for prolongation of pregnancy (clindamycin-treated group, 35.7 days gained; placebo-treated group, 19.0 days gained; p =0.07) and increased infant birth weight (clindamycintreated group, 2634 gm; placebo-treated group, 2296 gm; p = 0.1). There was a corresponding but statistically insignificant increase in gestational age at delivery (clindamycin-treated group, 35 weeks, placebo-treated group, 34 weeks; p = 0.16) and a corresponding decrease of low-birth-weight infants (clindamycin-treated group, 3/15 [20%]; placebo-treated group, 5/10 [50%]; p = 0.19) among clindamycin-treated women with bacterial vaginosis. Preterm birth occurred among 11 of 15 clindamycin-treated women (73.3%) who were initially found to have bacterial vaginosis versus 9 of 10 among similar placebo-treated women (90%).

Recovery of *M. hominis, U. urealyticum,* or *G. vaginalis* was not associated with prematurity or low birth weight. No treatment-associated differences in outcome variables were detected when presence of these microorganisms was controlled. Potential impact on studied pregnancy outcomes associated with the presence of group B streptococcus, *C. trachomatis, T. vaginalis,* and

S. aureus were not evaluated individually because of the small numbers of women from whom these microorganisms were identified.

To further define mother-perinate pairs who possibly benefited from clindamycin treatment, outcomes were categorized for women with microbes (other than bacterial vaginosis-associated microorganisms) such as group B streptococcus, C. trachomatis, T. vaginalis, or S. aureus that were previously implicated in premature birth. Each of these microorganisms, except for T. vaginalis, is susceptible to clindamycin. This subset of women with either group B streptococcus, C. trachomatis, T. vaginalis, or S. aureus was more likely to have preterm premature rupture of membranes after study entry than were women without these microorganisms (positive for microbes, 5/17 [30%]; negative for microbes, 7/86 [8%]; p = 0.01). Clindamycin treatment of these infected women reduced the incidence of preterm premature rupture of membranes to that of uninfected subjects (clindamycin-treated group, positive for microbes 1/9 [11%] and microbe negative for 4/44 [9%]; placebo-treated group, positive for microbes 4/8 [50%] and negative for microbes 3/42 [7%]). As noted, study outcomes did not correlate with the presence of amniotic fluid white blood cells among women undergoing amniocentesis (53%) either when considered alone or when study treatment was con-

Side effects were reported among 28% of clindamycin-treated women and 32% of placebo-treated women. Nausea and vomiting were the most common side effects, they occurred among 17% and 28% of clindamycin- and placebo-treated patients, respectively. Diarrhea (loose stools four to five times a day) was reported in five women (9.4%) who received clindamycin and in three women (6.0%) who received placebo. None of these women required discontinuation of treatment; no patient experienced pseudomembranous enterocolitis. Clostridium difficile toxin production was not detected. Two patients treated with clindamycin and one placebo-treated patient received treatment for yeast vulvovaginitis after study enrollment.

Comment

In this controlled trial we evaluated the efficacy, safety, and tolerance of a defined course of clindamycin versus placebo in prolonging pregnancy in hospitalized pregnant women treated with parenteral tocolysis ≤34 weeks' gestation. To further probe the effects of possible reproductive tract infection in mediating preterm birth, we also sought to identify obstetric and/or microbiologic parameters that identified women who benefited from clindamycin treatment. Pregnancies continued approximately 10 days longer in clindamycintreated women than in women receiving placebo (p = 0.02). Newborns of treated women required fewer days of level II or III nursing care (7.1 vs 16.8 days). Bacterial vaginosis was associated with a greater risk of preterm delivery. Women with group B streptococcus, C. trachomatis, T. vaginalis, or S. aureus were more likely to have subsequent preterm premature rupture of membranes. Clindamycin treatment was associated with reduced risk of preterm premature rupture of membranes in these women. Stratification for gestational age at enrollment showed that clindamycin was associated with a significantly prolonged interval to delivery only among women enrolled ≤32 weeks' gestation. Treatment appeared safe and well tolerated.

Limitations of this study include the number of subjects studied (103) and the inherent inability to precisely measure outcome variables, such as gestational age. End points, such as days to delivery or days of intensive nursery care, were more accurately determined than were clinically derived estimates of gestational length. Given the presumed heterogeneity of factors that cause preterm birth, many of which would not be affected by clindamycin treatment, a sample of 100 patients may be inadequate to detect other clinically relevant differences. For example, a sample of 66 women with bacterial vaginosis would be required to detect, with 80% probability, a significant increase in birth weight, with the assumption that the trend noted in this study was a true difference.

In spite of study limitations our finding of a 10-day overall prolongation of pregnancy associated with clindamycin treatment offers important benefits. In a large epidemiologic study Goldenberg et al.14 calculated that an infant's chance of surviving without major handicap increased up to 3% for each day of continued pregnancy between 23 and 30 weeks' gestation. Korenbrot et al.,15 who calculated direct costs, estimated that prolongation of pregnancy for women between 26 and 33 weeks' gestation resulted in savings of \$11,240 (in 1981) per birth. Hernandez et al.16 derived similar calculations in a Denver population. Total "costs" for preterm birth, including suffering and lost human potential for individual newborns, their families, and society, remain incalculable.

The microbiologic findings in this study confirm suggestions that bacterial vaginosis plays important roles in the pathogenesis of preterm birth. 17-20 Gravett et al. 17 reported findings of bacterial vaginosis among 43% of patients hospitalized with preterm labor versus 14% of matched control subjects without preterm labor. Subsequently, Martius et al.19 reported bacterial vaginosis in 55.7% of women with preterm labor who were delivered preterm compared with 15.6% of women who were delivered at term without preterm labor. In our study, preterm birth also occurred more frequently in the presence of bacterial vaginosis (p = 0.03). Newborns of clindamycin-treated women with bacterial vaginosis weighed a mean of 340 gm more than did infants of placebo-treated women. Failure of this dramatic difference to reach statistical significance should not overshadow the potential clinical benefits associated with prolongation of pregnancy. The relatively small number of women with bacterial vaginosis studied probably accounts for the lack of statistical significance.

Comparison of these findings with reported controlled trials of antibiotics among women in preterm labor suggests that responses differ in the various experimental antibiotic treatments and that factors mediating preterm birth probably vary among populations.⁸⁻⁶ We previously conducted a double-blind, randomized, placebo-controlled trial of oral erythromycin that demonstrated prolongation of pregnancy only among women with cervical dilatation ≥1 but ≤4 cm.3 In a similar study, Winkler et al.4 duplicated these findings and suggested that benefits occurred only among women with genital U. urealyticum. Subsequently, Morales et al.5 administered either ampicillin or erythromycin to a larger group of women and noted prolongation of pregnancy for each treatment group compared with untreated controls. They reported that only ampicillin treatment was associated with prolongation of pregnancy among G. vaginalis-colonized women, although the use of either antibiotic was associated with prolonged pregnancy in women with group B streptococcus but without G. vaginalis. Neither study specifically evaluated bacterial vaginosis or defined microbial findings after treatment.

In contrast, Newton et al.6 studied a predominantly Hispanic population and noted no benefit associated with intravenous ampicillin administered in addition to oral erythromycin.6 Bacterial vaginosis was common (41%). There was neither a reduction of these findings subsequent to treatment nor any improvement of pregnancy outcomes within this large subgroup. This suggests that effective treatment of bacterial vaginosis is linked to successful prolongation of pregnancy in women treated for preterm labor. Associations between group B streptococcus or other microbiologic findings and preterm birth were not discussed. In addition, fewer women in their study were delivered preterm (44% overall in the study by Newton et al.6 69% in the study by Morales et al.,5 and 62% in our study); this may have reduced the likelihood of detecting treatment effects.

In our study clindamycin treatment was associated with reduced identification of bacterial vaginosis and with the recovery of *M. hominis* but not *U. urealyticum*. In a prior non-treatment-based prospective study of microbiologic agents and complications of pregnancy, we noted an association between recovery of *M. hominis*

from the genital tract and bacterial vaginosis in women who subsequently had preterm labor. Recently, clindamycin has been shown to be an effective treatment for bacterial vaginosis. In our study clindamycin treatment remained in the multivariate regression model (p=0.03) and was associated with prolongation of pregnancy, regardless of cervicovaginal microbiologic findings. This suggests that clindamycin is effective against susceptible microorganisms that cause intrauterine infection (in the decidua or amniochorion) although not necessarily associated with the specific lower genital tract findings sought in our study.

Use of a defined course of intravenous (3 days) and subsequent oral (4 days) clindamycin may offer relative advantages in comparison with use of erythromycin and/or ampicillin. Use of oral medications among patients in labor may be associated with inadequate absorption that results from a delay in gastric emptying or vomiting, especially in women treated with tocolytics. The pharmacokinetics of clindamycin during pregnancy are well studied. Clindamycin also provides relatively focused antimicrobial coverage for agents previously implicated in preterm birth, including bacterial vaginosis, group B streptococcus, C. trachomatis, and genital mycoplasmas (especially M. hominis), as well as a broad variety of anaerobic bacteria. 17-20

Other features of clindamycin use also may offer relative advantages in the treatment of preterm labor. Unlike erythromycin, clindamycin is functionally active at pH conditions common in the vagina and readily crosses the placental barriers to achieve therapeutic concentrations within gestational tissues and amniotic fluid.23, 24 In contrast to ampicillin, clindamycin is concentrated relative to maternal serum within the amnion and chorion.25 This may prove important, because Hillier et al.20 showed that microorganisms were recovered between layers of amniochorion in more than half of women who were delivered before 32 weeks' gestation.20 Clindamycin also may nonspecifically enhance maternal-host defenses. Clindamycin penetrates into polymorphonuclear leukocytes, increases intercellular killing or inhibition of bacteria, and reduces adherence among various microorganisms.26 Such features suggest that clindamycin or similar agents may provide selective advantages and benefits in treatment of instances of preterm labor attributable to reproductive tract infection. Conversely, the use of β-lactam antibiotics, such as ampicillin, may hasten processes involved in preterm labor. These agents effect bacterial cell lysis, with subsequent release of bacterial contents, and may foster further tissue damage. Use of antibiotics such as clindamycin and ampicillin has been associated with antibiotic-induced diarrhea, including C. difficile toxin-associated pseudomembranous enterocolitis.

In our study treatment with an adjunctive-defined

course of clindamycin was associated with significant prolongation of pregnancy in hospitalized women treated for preterm labor. This effect appeared to be limited to women enrolled at ≤32 weeks' gestation. Additional studies are required to confirm these findings and to refine indications for appropriate antimicrobial treatment for women at risk for preterm birth. Studies to evaluate whether significant numbers of preterm births can be prevented by effective treatment of reproductive tract infection either early in pregnancy or before pregnancy are ongoing.

We thank Ms. Cheryl Welch and Ms. Rosie Vu for their preparation of this manuscript.

Fetal cardiac function in intrauterine growth retardation

Giuseppe Rizzo, MD, and Domenico Arduini, MD

Rome, Italy

Blood-flow velocity waveforms are altered in several peripheral vascular beds of fetuses whose intrauterine growth is retarded because of placental insufficiency. We investigated these concomitant changes in cardiac function. Color and pulsed Doppler echocardiographic recordings were performed in 124 fetuses with intrauterine growth retardation. These fetuses were free of structural and chromosomal abnormalities and were characterized by increased umbilical artery resistance and reduced middle cerebral artery resistance. Twenty-four of these fetuses were also studied at weekly intervals until the onset of antepartum late heart rate decelerations. Blood-flow velocity waveforms were obtained from the aortic and pulmonary valves, and the following variables were measured: peak systolic velocity, time to peak velocity, the product of time velocity integral multiplied by heart rate, left and right cardiac output, and the right/left ratios of the product of time velocity integrals multiplied by heart rate and cardiac output. When compared with previously established norms, both aortic and pulmonary peak systolic velocities and pulmonary time to peak velocity were reduced; aortic time to peak velocity increased. Left cardiac output and the product of the aortic time velocity integral multiplied by the heart rate increased and right cardiac output and the product of the pulmonary time velocity integral multiplied by the heart rate decreased, resulting in reduced right/left ratios. In the 24 fetuses studied longitudinally, time to peak velocities and the right/left flow ratios remained stable. However, aortic and pulmonary peak velocities and cardiac output declined significantly in contrast to an expected rise with advancing gestation. The fall in cardiac output and aortic and pulmonary peak velocities was directly related to umbilical artery pH at birth. This study provides evidence of a modified cardiac function that seems to deteriorate progressively with the advancing gestation of fetuses with intrauterine growth retardation. (AM J OBSTET GYNECOL 1991;165:876-82.)

Key words: Intrauterine growth retardation, Doppler ultrasonography, fetal heart, echocardiography

Intrauterine growth retardation (IUGR) caused by placental insufficiency is associated with altered Doppler blood flow velocity waveforms in several vascular beds, including the umbilical artery, descending aorta, renal artery, and cerebral vasculature. These changes suggest selective modification of peripheral vascular resistance, which leads to preferential perfusion of the brain with respect to the lower body (i.e., the so-called brain-sparing condition).

Little study has been done on cardiac function in IUGR, and the findings obtained are controversial. Reed et al.⁵ observed increased right cardiac output, and we⁶ and Al Ghazali et al.⁷ observed a redistribution of cardiac flow in favor of the left side of the heart. These earlier studies used different criteria for the selection of fetuses, and their sample sizes were relatively small. The purpose of our investigation was twofold:

first, to elucidate the changes of cardiac function present in IUGR caused by placental insufficiency; and second, to discover the possible further modifications of cardiac function from the time IUGR is diagnosed to the onset of antepartum late heart rate decelerations.

Material and methods

Subjects. After we obtained informed consent from the mothers, 124 fetuses with IUGR were evaluated (Table I). Entry criteria were (1) singleton gestation accurately dated by early second-trimester fetal biparietal diameter measurement; (2) abdominal circumference <5th percentile of our reference limits (fetuses with a gestational age <28 weeks) or ultrasonographically estimated fetal weight (fetuses with a gestational age ≥28 weeks) <5th percentile for our population; (3) absence of congenital or chromosomal abnormalities; and (4) abnormal blood flow velocity waveforms suggesting brain sparing (i.e., ratio of umbilical artery/middle cerebral artery pulsatility index >95th percentile for our reference limits).8 The diagnosis of IUGR (i.e., birth weight <5th percentile in a newborn free of structural abnormalities) was postnatally confirmed in all subjects.

It was also possible to study longitudinally a subgroup of these pregnancies at weekly intervals from the diagnosis of IUGR until delivery. To obtain a homoge-

neous group, we retained only the data of 24 fetuses who had antepartum late heart rate decelerations and who had been studied on at least four occasions I week apart (longitudinal study) (Table I). Fetal heart rate monitoring was performed daily for ≥45 minutes from the time of diagnosis. At the onset of late heart rate decelerations during Braxton Hicks contractions, elective cesarean sections were performed. For control, 26 healthy fetuses were similarly studied at weekly intervals from 27 to 33 weeks' gestation.

Umbilical artery pH was measured at delivery in 94 fetuses with IUGR (21 belonging to the longitudinal subgroup) on double-clamped segments of the cord. All measurements were performed ≤5 minutes from delivery with an automated blood gas analyzer (ABL 30, Radiometer A/S, Copenhagen).

Doppler echocardiographic examination. Commercially available color Doppler echocardiographic equipment (Esacord 81, Ansaldo Hitachi, Genoa) with a 3.5 or 5 MHz convex probe was used for all measurements. In addition to the color flow mapping function, the machine was equipped with a pulsed Doppler instrument with a carrier frequency that ranged from 2.5 to

Velocity waveforms were recorded in the ascending aorta and pulmonary artery according to a previously reported technique.9 The aortic valve was visualized on the five-chamber view, and the pulmonary valve was visualized on the short-axis view. The color flow mapping function was superimposed and the valve flow measured. Care was taken to visualize flow so that it was parallel to the Doppler echocardiographic beam. The sample site was just distal to the valve leaflets. Recordings obtained with a beam angle >20 degrees were rejected.

Doppler echocardiographic and real-time images were recorded on standard half-inch videotape for subsequent analysis. Valve diameter measurements were made at playback of videorecorded images frozen during diastole at the tip of the closed arterial valve. Measurements were performed at 10 different cycles for each valve, and the values were averaged. Valve area was calculated by assuming a circular cross section.

Permanent records of the velocity waveforms were made on a strip chart recorder from the videotape. Ten consecutive velocity waveforms were selected during periods of fetal rest without breathing movements, and the values were averaged (Fig. 1). The following variables were measured with the aid of a computer-interfaced digitizer pad (Cardio 800, Kontron Instruments, Oxford, England): (1) peak velocities during systole; (2) time to peak velocity, calculated as the time difference from the onset of the waveform to its peak velocity⁷; (3) time velocity integral; and (4) heart

No. admitted to neonatal intensive care unit (%)	24 (100)

per minute) was calculated by multiplying the pulmonary or aortic time velocity integral, valve area, and heart rate. Because valve area calculations have a relatively high coefficient of variation,7.10 cardiac flow was also expressed as the product of time velocity integral multiplied by heart rate, an index related to absolute cardiac output.11 Last, the combined cardiac output (left cardiac output plus right cardiac output) and the ratios between right cardiac output and left cardiac output and between the pulmonary time velocity integral multiplied by heart rate and aortic time velocity integral multiplied by heart rate were calculated.

To correct cardiac output for fetal size, the combined cardiac output was corrected for fetal weight and expressed as milliliters per minute per kilogram. However, because the ultrasonographic estimation of fetal weight may add a source of error to the difficult calculation of cardiac output, this analysis was limited to the last recording performed in the fetuses with IUGR who were studied longitudinally. In this instance we used the neonatal weight.

Data analysis. The variables measured were com-

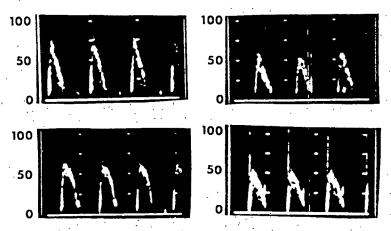

Fig. 1. Flow velocity waveforms recorded at 34 weeks' gestation at aortic valve level (top panel) in normal fetus (right: peak velocity = 77 cm/sec, time to peak velocity = 43 msec) and fetus with IUGR (left: peak velocity = 58 cm/sec, time to peak velocity = 61 msec) and at pulmonary valve level (bottom panel) in normal fetuses (right: peak velocity = 61 cm/sec, time to peak velocity = 38 msec) and fetus with IUGR (left: peak velocity = 51 cm/sec, time to peak velocity = 21 msec). Values are in centimeters per second.

pared with our reference population of 197 normal fetuses between 20 and 40 weeks' gestation. ^{10, 12} Differences were evaluated by means of one sample and unpaired Student's t tests. The longitudinal changes in echocardiographic parameters were evaluated by the analysis of variance for repeated measurements. Simple and multiple regression analyses were used to test the relationships between the variables considered. Differences yielding $p \le 0.05$ were considered significant.

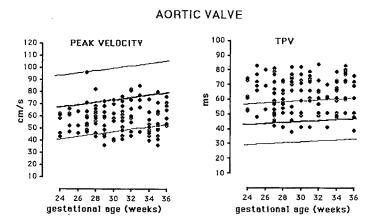

Results

Cross-sectional study. Successful recordings were obtained in 121 (97.6%) fetuses at the aortic valve level and in 116 (93.5%) at the pulmonary valve level. Peak velocity values recorded at the aortic (t = 8.341, $p \le 0.001$) and pulmonary ($t = 8.973, p \le 0.001$) valve levels for fetuses with IUGR were significantly lower than for our reference populations (Fig. 1). Aortic time to peak velocity was higher (t = 14.779, $p \le 0.001$) and pulmonary time to peak velocity lower (t = 9.546, $p \le 0.001$) than normal in fetuses with IUGR (Fig. 2). Aortic time velocity integral multiplied by heart rate $(t = 2.643, p \le 0.01)$ and left cardiac output $(t = 2.348, p \le 0.01)$ $p \le 0.02$) were significantly higher in IUGR compared with control fetuses. Pulmonary time velocity integral multiplied by heart rate ($t = 1.989, p \le 0.05$) and right cardiac output (t = 2.371, $p \le 0.02$) were lower in fetuses with IUGR. No significant changes were found in combined cardiac output (t = 0.881, not significant [NS]). A consequence of the increased left flow associated with the decreased right flow was that the right cardiac output/left cardiac output (t = 18.947, $p \le$ 0.001) and pulmonary time velocity integral multiplied by heart rate/aortic time velocity integral multiplied by

heart rate (t = 15.729, $p \le 0.001$) ratios were reduced in IUGR (Fig. 3).

Longitudinal study. Pregnancy outcome and delivery were uneventful for the control fetuses. Their gestational age (mean \pm SD) at delivery was 40.3 ± 1.8 weeks; birth weight was 3345 ± 435 gm. In these fetuses the pulsatility index from the umbilical artery decreased with advancing gestation (F = 7.123, $p \le 0.001$), and the pulsatility index of the middle cerebral artery was unchanged (F = 1.212, NS). As a result, the ratio between the umbilical artery and the middle cerebral artery pulsatility index significantly decreased (F = 2.435, $p \le 0.005$). At the intracardiac level, peak velocity at the aortic (F = 2.012; $p \le 0.01$) and pulmonary (F = 1.987, $p \le 0.01$) valve levels rose progressively with advancing gestation. Similarly left cardiac output (F = 18.639, $p \le 0.001$), right cardiac output (18.457, $p \le 0.001$), aortic time velocity integral multiplied by heart rate (F = 2.194, $p \le 0.005$), and pulmonary time velocity integral multiplied by heart rate (F = 2.077, $p \le 0.01$) rose with gestational age. Over the interval studied, no significant alterations in aortic time to peak velocity (F = 0.463, NS), pulmonary time to peak velocity (F = 0.784, NS), right cardiac output/left cardiac output (F = 0.521, NS), and pulmonary time velocity integral multiplied by heart rate/aortic time velocity integral multiplied by heart rate ratio (F = 0.437, NS) were seen.

IUGR fetuses showed a significant increase in the umbilical artery pulsatility index (F = 2.022, $p \le 0.01$) and a significant decrease in the middle cerebral artery pulsatility index (F = 1.931; $p \le 0.01$). Therefore the ratio between the umbilical artery and middle cerebral artery increased further (F = 2.424, $p \le 0.005$). Peak

PULMONARY VALVE .

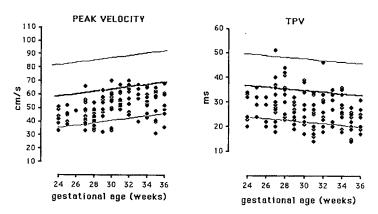

Fig. 2. Aortic and pulmonary peak velocity and time to peak velocity (TPV) values in fetuses with IUGR plotted on our reference ranges for gestation (mean and 95% confidence intervals).

velocity values at both the aortic (F = 11.423, $p \le 0.001$) and pulmonary (F = 9.358, $p \le 0.001$) valve levels declined progressively in fetuses with IUGR (Fig. 4). Furthermore, the left cardiac output (F = 8.267, $p \le 0.001$), right cardiac output (F = 7.975, $p \le 0.001$), combined cardiac output (F = 14.676, $p \le 0.001$), aortic time velocity integral multiplied by heart rate (F = 12.358, $p \le 0.001$), and pulmonary time velocity integral multiplied by heart rate (F = 10.755, $p \le 0.001$) decreased significantly with advancing gestation. No significant variations were found in aortic (F = 0.699, NS) and pulmonary (F = 0.730, NS) time to peak velocity values, and in right cardiac output/left cardiac output (F = 0.586, NS) and pulmonary time velocity integral multiplied by heart rate/aortic time velocity integral multiplied by heart rate ratios (F = 0.974, NS). The individual changes of aortic peak velocity, pulmonary peak velocity, and combined cardiac output found in IUGR are plotted in Fig. 4. When the combined cardiac output of fetuses with IUGR obtained at the last recording was corrected for neonatal weight and compared with the

control group, a statistically significant difference was proved (IUGR combined cardiac output = 395 ± 124 ml/min/kg; control combined cardiac output = $525 \pm 96 \text{ ml/min/kg}$; t = 6.05; $p \le 0.001$). The echocardiographic parameters obtained during the last recording were corrected for gestational age (i.e., number of standard deviations by which they differ from the expected mean of gestation) and related to umbilical artery pH at birth. A positive correlation was found between pH and peak velocity in ascending aorta $(r = 0.43; p \le 0.05)$, peak velocity in pulmonary artery (r = 0.51; $p \le 0.03$), and combined cardiac output values (r = 0.67; $p \le 0.01$) with a multiple correlation coefficient of 0.71. No significant relationships were noted between the severity of IUGR (as evident in the birth weight percentile) and the Doppler echocardiographic examination variables considered.

Comment

During fetal life, the output of the left ventricle is directed through the ascending aorta mainly to the brain, whereas the output of the right ventricle is di880 Rizzo and Arduini

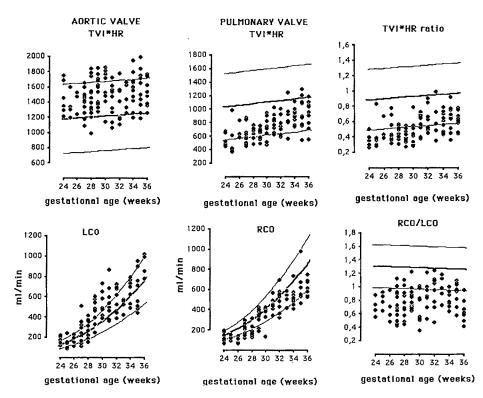

Fig. 3. Products of time velocity integral multiplied by heart rate (TVI*HR) in aortic and pulmonary valves, left (LCO) and right (RCO) cardiac output, right/left ratio of products of time velocity integrals multiplied by heart rate (TVI*HR ratio) and ratio of cardiac output (RCO/LCO) in fetuses with IUGR plotted on our reference ranges for gestation (mean and 95% confidence intervals).

rected through the ductus arteriosus to the lower body and placenta. Previous Doppler echocardiographic studies and the present longitudinal data have shown that in normal fetuses, peak flow velocity rises with gestation at both the aortic and pulmonary valves. These changes are probably caused by several factors, including a progressive improvement in myocardial contractility, a reduction of cardiac afterload, and an increase in cardiac preload. 13, 14 Study of the time to peak velocity (a parameter inversely related to blood pressure) suggests that in healthy fetuses, the mean pressure is slightly higher in the pulmonary artery than in the ascending aorta.15 Finally, it has been shown that cardiac output increases progressively with gestation and that right cardiac output is slightly higher than left cardiac output, with a right cardiac output/left cardiac output ratio of about 1.3.13, 16

Doppler echocardiographically measured cerebral vascular resistance in fetuses whose IUGR is caused by placental insufficiency is lower than normal and the placental resistance is higher than normal, suggesting that there is a selective change in cardiac afterload (i.e., decreased left ventricular and increased right ventricular afterload). IUGR caused by placental insufficiency is frequently associated with both hypoxemia, which may impair cardiac contractility, 7 and polycythemia, 18

which could alter viscosity and therefore cardiac preload.

Both the selection criteria and the pregnancy outcome strongly suggest that the growth defects of the fetuses in this study resulted from placental insufficiency. These fetuses with IUGR showed reduced peak velocity, increased aortic and decreased pulmonary time to peak velocity, and a relative increase of left cardiac flow associated with decreased right cardiac flow. These data confirm previous results in smaller series of fetuses with IUGR.^{6, 7, 9, 19}

The parameters measured in this study are influenced by various factors such as preload, afterload, intrinsic contractile properties of the left and right ventricles, and valve dimensions. The noninvasive nature of the human fetal model does not allow further differentiation between these factors.

There has been debate as to whether time to peak velocity values in the human fetus reflect mainly the pressure in the aorta and the pulmonary artery, and therefore the impedance and capacitance of the distal vascular districts, or whether they are also influenced by the intrinsic contractile properties and preload conditions of the two ventricles. ^{15, 20} The lack of data on simultaneous measurements of flow and pressure does not allow us to differentiate between these explana-

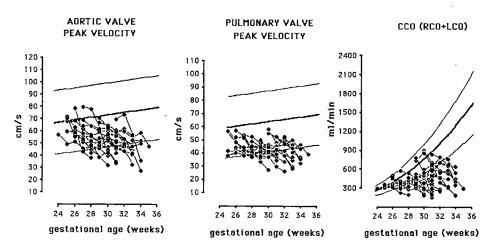

Fig. 4. Individual changes in aortic and pulmonary peak velocity and in combined cardiac output (CCO = left plus right cardiac output) values in the 24 fetuses with IUGR studied longitudinally plotted on our reference ranges for gestation (mean and 95% confidence intervals). Values of each patient are connected by lines.

tions. However, the inverse modifications of pulmonary and aortic time to peak velocity suggest the presence of different functional conditions between the right and left ventricles in fetuses with IUGR. This justifies the preferential shift of cardiac output in favor of the left ventricle, leading to improved perfusion to the brain. Thus the supply of substrate and oxygen could be maintained at near-normal levels in spite of any absolute reduction of placental transfer. The reduced peak velocity values could have multiple causes, including decreased myocardial contractility, modifications of preload, pressure, volume flows, and valve dimension.

Doppler echocardiographically derived estimates of hemodynamic parameters in the human fetus must be interpreted with caution because absolute calculations of volume flows are prone to error resulting from the inaccuracies in determining valve diameters (which are then halved and squared in the calculation). However, we sought to minimize this bias by eliminating the measurement of valve area from the calculation (time velocity integral multiplied by heart rate). The results were unaltered and thus supported the reliability of our findings.

Contradictory findings were reported by Reed et al.,5 who observed increased flow in the right side of the heart in a study of 12 fetuses selected on the basis of absent umbilical artery end-diastolic velocities. However, four fetuses in this series had chromosomal or structural abnormalities and four showed either pericardial or pleural effusions, suggesting that many of the fetuses studied had IUGR that was not solely the result of placental insufficiency. This conclusion is supported by previous Doppler echocardiographic studies that showed the absence of brain sparing in fetuses with IUGR who also had structural or chromosomal abnormalities in spite of abnormalities in umbilical artery velocity waveforms.21.22 A difference in the adaptive vascular mechanism might explain the discrepancy in the cardiac studies.

In both the cross-sectional evaluation and the first recording of the longitudinal study, fetuses with IUGR showed combined cardiac output values similar to those of normal fetuses of corresponding gestational age, implying relatively higher output with respect to fetal weight. These findings confirm a prior report and suggest that in a first step of the disease (the interval between the Doppler echocardiographic recordings and delivery in the cross-sectional study was >3 weeks [range 1 to 7 weeks]) the cardiac output is not only diverted toward the left side but also is relatively in-

Our longitudinal study of fetuses with IUGR allowed us to elucidate the natural history of cardiovascular modifications. Because the time to peak velocity and the ratios between right and left ventricular flows remained stable, it appears that there are no other significant changes in outflow resistance and cardiac output redistribution after the establishment of the brainsparing mechanism in spite of the further worsening of the ratio between the umbilical artery and the middle cerebral artery pulsatility index. However, it is important to note that in IUGR peak velocity and cardiac output progressively declined rather than rising with gestation as expected, and the fall of combined cardiac output values obtained at the last recording were also significantly lower after correction for weight. Similarly, studies in animals showed a significant reduction of cardiac output during chronic preparations designed to retard fetal growth.23 A significant correlation has been found between the reduction of peak velocity in the pulmonary artery and the severity of placental infarction in the human fetus.¹⁹

The physiologic significance of these longitudinal changes is subject to several interpretations. Because they are closely followed by the onset of abnormal heart rate patterns and are related to umbilical artery pH at birth, we speculate that the fall in cardiac output and in peak velocity terminally may be related to a progressive compromise of fetal oxygenation and acid-base status.

In conclusion, abnormalities of cardiac function are present in fetuses with IUGR caused by placental insufficiency; they differ between the right and left ventricles. In fetuses studied longitudinally until the onset of spontaneous late heart rate decelerations a further decrease of cardiac output and pulmonary and aortic peak velocities was found.

When do cardiovascular parameters return to their preconception values?

Eleanor L. Capeless, MD, and James F. Clapp, MD

Burlington, Vermont

To determine if the postpartum period is reflective of a woman's cardiovascular status before pregnancy, we performed serial studies of 13 women before conception and at 6 and 12 weeks post partum. All pregnancies were singleton without hypertensive complications. Cardiac output, stroke volume, and end-diastolic volume were calculated with M-mode echocardiography from the left ventricular dimensions with subjects in the left lateral position. Systemic vascular resistance was calculated from cardiac output and simultaneous measurements of blood pressure. Stroke volume and end-diastolic volume remained consistently elevated over preconception values at 6 and 12 weeks. Systemic vascular resistance remained decreased, compared with baseline, at 12 weeks. Thus cardiovascular parameters had not returned to the preconception baseline, and previous studies that have used this time period for comparison have underestimated the contribution of stroke volume to the total change in cardiac output during pregnancy. (AM J OBSTET GYNECOL 1991;165:883-6.)

Key words: Maternal echocardiography, pregnancy, postpartum period, cardiovascular

The cardiovascular system undergoes profound alterations during pregnancy. Increases in heart rate, stroke volume, end-diastolic volume, and cardiac output and decreases in mean arterial pressure and systemic vascular resistance have been well documented with several different techniques. ¹⁻³ However, previous studies may have underestimated the magnitude of the cardiovascular changes in pregnancy, because baseline measurements were not obtained before pregnancy but rather were compared with postpartum values. It has not been established when or whether cardiovascular function returns to its preconception state. This study was undertaken to address this issue.

We have previously reported on the cardiovascular changes in early pregnancy determined with M-mode echocardiography. When subjects were studied before pregnancy and serially during pregnancy, significant increases in stroke volume, left ventricular end-diastolic volume, and cardiac output could be documented in the first trimester. Robson et al., with Doppler and M-mode echocardiography, have documented similar changes when subjects were initially studied before pregnancy and serially during pregnancy. This report extends our earlier studies to include the postpartum

6/6/31183

period. We hypothesized that the central cardiovascular changes that occur in pregnancy do not return to their baseline state by 6 weeks post partum. A longitudinal serial study design in which each subject was studied before conception was used so that comparisons could be based on each subject's preconception baseline.

Material and methods

Thirteen subjects were initially evaluated within 3 months of conception. All subjects were nonsmoking, physically active women with no history of heart disease, and all were delivered of singleton infants after 37 weeks without hypertensive complications. All women were breast-feeding when studied at 6 and 12 weeks post partum. The mean age was 30.6 years, with a range of 25 to 36 years. There were seven primiparous and six multiparous women.

All studies were preceded by an initial 15-minute accommodation to the laboratory environment. At this time, a heart rate monitor and blood pressure cuff were placed, and the subject assumed a comfortable left lateral position. Blood pressure was measured every 2 minutes with a mercury sphygomomanometer that was zeroed at the level of the subject's left ventricle. M-mode echocardiography was performed with either a GE 3600 or an ADR Ultramark 4 ultrasonography machine. The left parasternal window was used to obtain the long-axis view of the heart, which visualized the left ventricle and the mitral and aortic valves with real-time scanning. The M-mode beam was then positioned just below the tips of the mitral valve leaflets. Measurements of end-systolic and end-diastolic dimensions were made in accordance with the guidelines published by the

Table I. Cardiovascular measurements

	Before pregnancy	6 wk post partum	12 wk post partum
End-diastolic volume (ml)	107 ± 6	124.1 ± 7*	119 ± 5*
Stroke volume (ml)	68 ± 3	81 ± 4*	79 ± 3*
Cardiac output (L/min)	4.3 ± 0.2	4.6 ± 2	$4.9 \pm 0.2\dagger$
Heart rate (beats/min)	64 ± 2	57 ± 3	62 ± 3
Mean arterial pressure (mm Hg)	70 ± 2	74 ± 3	69 ± 3
Systemic vascular resistance (dynes × sec × cm ⁻⁵)	1349 ± 83	1277 ± 65	1154 ± 70*

Values are mean ± SEM.

American Society of Echocardiography.⁶ An additional 5 minutes of imaging preceded the initial measurements in an effort to further accommodate the subject to the study. Heart rate was directly measured during the intervals in which cardiac output was determined. Three or more separate sets of measurements were obtained over a 15-minute period. Thus the values obtained represent the average of 27 to 50 separate cardiac cycles interspersed throughout the respiratory cycle.

Left ventricular volumes were calculated from the end-diastolic and end-systolic dimensions in accordance with the formula of Teichholz et al. for a modified prolate ellipsoid. These data were then used to calculate stroke volume, cardiac output, mean arterial pressure, and systemic vascular resistance with standard formulas.

The calculations of stroke volume with the Teichholz equation has been validated against angiography-derived stroke volume with a correlation coefficient of r=0.97.7 When the technique was compared with thermodilution cardiac output, the correlation coefficient was r=0.86.8 Thus, with a normally shaped ventricle and uniform contraction of the ventricular wall, the measurement obtained should accurately reflect left ventricular volume changes. The variability of this technique between the two investigators and the variability of successive measurements over the individual study period averaged 6%.

Repeated-measures analysis of variance was used to determine the significance associated with observed differences in the various dependent measures at the three time points (before pregnancy and 6 and 12 weeks post partum). If the overall analysis of variance resulted in statistical significance (p < 0.05), Fisher's least-significant difference procedure was used to further evaluate the specific comparisons of interest (before pregnancy vs 6 weeks post partum and before pregnancy vs 12 weeks post partum). Comparisons were performed on least-square means with a Bonferroni adjustment to control the type I error rate. Analyses were performed with SAS statistical software.

Results

The results (mean \pm SEM) of the serial cardiovascular measurements are presented in Table I. Enddiastolic volume was significantly increased at both 6 and 12 weeks post partum (16% and 12%). Similar significant increases were seen in stroke volume at both time periods (19% and 16%). Cardiac output was also elevated but to a lesser extent because of a 9% decrease in heart rate seen at 6 weeks post partum, but because the heart rate increased at 12 weeks post partum the increase in cardiac output (14%) was statistically significant at this time period. There was no difference in mean arterial pressure when compared at the different time periods. Systemic vascular resistance remained decreased at both 6 (-6%) and 12 (15%) weeks post partum with statistical significance attained at 12 weeks. The changes in maternal weight were variable. Although the group averaged an increase above pregravid weight of 6 kg at 6 weeks post partum and 3 kg at 12 weeks post partum, 30% and 38% were within 1 kg of pregravid weight at these study periods. There was no difference in cardiovascular response between those whose weight remained elevated over pregravid weight and those whose weight returned to pregravid levels. When the data were corrected for body surface area, the significance remained. There was no difference in cardiovascular response between primiparous and multiparous women.

Comment

Although there have been many serial studies of cardiovascular parameters during pregnancy, few have followed with serial measurements in the postpartum period. ^{1-3, 9, 10} This is the first report of these parameters measured by M-mode echocardiography that included the same population both before pregnancy and in the postpartum period. This study documents that some changes associated with pregnancy have not regressed by 12 weeks post partum when compared with values before pregnancy in lactating women. It is not known when these changes return to their baseline state or if there are permanent changes that occur as a result of

^{*}p < 0.01, compared with value before pregnancy.

 $[\]dagger p = 0.024$, compared with value before pregnancy.

pregnancy. There is accumulating evidence in both humans and animals that the cardiovascular system may undergo remodeling in response to pregnancy. Hart et al.11 have found that multiparous women have larger aortic diameters than do primiparous women, suggesting that there are alterations that occur during pregnancy and do not revert to their prepregnancy baseline. Robson et al.9 have documented differences in left ventricular wall thickness and mass between postpartum values and those obtained in a nonpregnant control group. Sady et al.10 found no difference in cardiac output and stroke volume when compared in the same women at 2 and 7 months post partum. Remodeling of the left ventricle has been shown to occur in the guinea pig during pregnancy12, 13 and during estrogen administration. 12 Davis et al. 14 demonstrated in the guinea pig that mean circulatory filling pressure does not change during pregnancy, but total body compliance and unstressed volume increases. These studies suggest that the pregnancy-induced increase in stroke volume and cardiac output may not be in response to increased preload by the Starling mechanism but that both the ventricle and the venous system have undergone remodelling. This concept has been supported by Hohman et al.¹⁵ in the rat model, who demonstrated structural changes in the vessel wall of the venous system in response to pregnancy. Thus permanent alterations in the cardiovascular system may be evoked by normal pregnancý.

Robson et al.9 have also studied hemodynamic changes serially from late pregnancy (38 weeks) through 24 weeks post partum (2, 6, 12, and 24 weeks). Initial significant decreases were found in all parameters studied by 2 weeks post partum but there was little change in stroke volume, end-diastolic dimension, and cardiac output between 6 and 12 weeks. This agrees with the trends seen in our group. They found no difference between breast-feeding and non-breastfeeding women. When compared with values in a nonpregnant control group, aortic and pulmonary valve area, aortic and mitral stroke volume, total left ventricular wall thickness, and left ventricular mass were significantly increased.

Indirect support for our findings of elevated stroke volume, end-diastolic volume, and possibly cardiac output in the postpartum period can be obtained by a comparison of the pregnancy study by Robson et al.5 with the postpartum study by the same investigator.9 The magnitude of the increases in stroke volume, enddiastolic volume, and cardiac output that were present when preconception values were compared with pregnancy were not matched by similar decreases when pregnancy values were compared with those found at 6 and 12 weeks post partum. Thus these parameters remain elevated above preconception values. These findings have important implications in the interpretation of previous studies1-3 of cardiovascular parameters during pregnancy. The postpartum period has been accepted as the baseline state; therefore the continued increase in stroke volume at this time period would serve to underestimate its contribution to the total increase in cardiac output seen in pregnancy.

M-mode echocardiography is a noninvasive technique that can serially follow changes in cardiovascular parameters.8. 16 Previous studies have documented excellent correlation of M-mode echocardiography with both angiography7, 16-derived stroke volume and thermodilution⁸ cardiac output. With a normally shaped ventricle and uniform contraction of the ventricular wall, the measurement obtained should accurately reflect left ventricular volume changes.9 In our experience with normal women, it has proved highly reproducible. In addition, the values obtained in our study for cardiac output and stroke volume are comparable to those of Robson et al.5 and Katz et al.2

The heart rate response seen in our study was variable. We observed a decrease (6 beats/min) at 6 weeks after delivery with an increase at 12 weeks to a level similar to preconception values. This disagrees with Robson et al.,9 who found no change throughout the puerperium yet agrees with Sady et al.,10 who in an exercising populace found an initial decrease in heart rate at 8 weeks compared with 7 months post partum.

In summary, we have found that left ventricular enddiastolic volume and stroke volume remain elevated over their values before conception when measured in the same populace both before and after a normal pregnancy. The effect of a pregnancy complicated by hypertension is an area for future study.

Baroreflex function in normal pregnancy

Line Leduc, MD, Nathan Wasserstrum, PhD, MD, Thomas Spillman, PhD, and David B. Cotton, MD

Houston, Texas

The sinoaortic baroreflex is one of the primary mechanisms that regulates blood pressure. Decreased baroreflex sensitivity has been reported in preeclampsia. We sought to determine whether pregnancy altered baroreflex sensitivity. From a radial artery catheter, heart rate and mean arterial pressure were recorded continuously onto a polygraph. The ratio of change in heart rate produced per unit of change in mean arterial pressure was calculated as an index of baroreflex sensitivity. Mean arterial pressure responses to incremental infusions of phenylephrine (0.4 to 2.0 μ g/kg/min) were measured in the same patients at term (n=9, 38.0 \pm 0.3 weeks) and again 6 to 8 weeks post partum (n=7). The results indicated (1) higher baroreflex sensitivity in pregnancy than in the postpartum period (0.9 vs 0.5 beats/min/mm Hg) (ρ < 0.007); (2) attenuated vascular responsiveness to α -adrenergic stimulation in pregnancy (ρ < 0.05); (3) a relationship between vascular responsiveness and baroreflex sensitivity. We conclude that pregnancy is associated with an increase in baroreflex sensitivity and that the attenuated response to phenylephrine is, at least in part, a result of increased baroreflex sensitivity. (AM J OBSTET GYNECOL 1991;165:886-90.)

Key words: Baroreflex sensitivity, baroreceptor, normal pregnancy

Short-term regulation of blood pressure is normally effected by the sinoaortic baroreflex. Stimulation of stretch receptors, which are located mainly in the aortic arch and carotid sinuses, causes reflex bradycardia and peripheral vasodilatation. The sensitivity of this reflex can be assessed from the ratio of change in

heart rate produced per unit of change in blood pressure.^{1, 2}

Physiologic states such as sleep³ and exercise⁴ are associated with resetting of the baroreflex. Numerous studies⁵⁻⁷ also have reported baroreflex resetting with aging⁸ and after long-term exposure to chronic hypertension.

In addition to resetting of the barostat, certain conditions are associated with changes in reflex sensitivity. Loss of sensitivity implies weaker neuroanatomic control of the circulation in response to any acute perturbation.

Pregnancy-induced hypertension recently has been associated with loss of baroreflex sensitivity. 9. 10 The he-

modynamic instability characteristic of pregnancy-induced hypertension and the associated increased vascular reactivity to vasoactive agents may result from loss of baroreflex sensitivity.10

Seligman⁹ reported higher baroreflex sensitivity in normal pregnancy than in pregnancy-induced hypertension. However, the sensitivity during pregnancy was not compared with that of the nonpregnant state. We sought to quantify the baroreflex sensitivity in normal pregnancy and to determine whether pregnancy alters baroreflex sensitivity.

Material and methods

The protocol was approved by the Baylor College of Medicine Institutional Review Board for Human Investigation, and patients who participated in the study gave written consent. Nine carefully chosen patients with normal pregnancy at term were enrolled. Patients with medical problems or patients with any indication of an abnormal fetal heart rate pattern were excluded from this protocol. A reactive nonstress test and a biophysical profile score of 8/8 were required for entry into the study. The maternal age ranged from 17 to 31 years (mean \pm SD, 24 \pm 2), and the gestational age ranged from 36 to 39.4 weeks (mean \pm SD, 38.0 ± 0.3). Four of the nine patients were primigravid.

The radial artery was cannulated. Pressure transducers (Transpac II, Abbott Critical Care Systems, Sorenson, Chicago) were calibrated with the zero reference point at the midaxillary line. Continuous mean arterial pressure and heart rate were recorded on a twochannel recorder (model 2200S, Gould, Valley View, Ohio). Continuous fetal monitoring was performed during the entire study.

All measurements were recorded with the patient in a 15-degree left lateral decubitus position, and the head was raised to 30 degrees. For purposes of analysis, successive measurements of mean arterial pressure and corresponding heart rate were taken at baseline, every 10 minutes during the phenylephrine infusion, at the end of the infusion, and after a recovery interval for 30 minutes. Baroreflex sensitivity was derived from the change in heart rate associated with a change in mean arterial pressure during infusion of a pure α-adrenagonist, phenylephrine (Neo-Synephrine, Winthrop, New York).

Phenylephrine was diluted in 5% dextrose in water and infused at incremental doses ranging from 0.4 to 2.0 µg/kg/min. The rate of infusion was controlled with a variable rate Harvard infusion pump (Harvard, Dover, Mass.). The increment of phenylephrine was based on the individual patient's blood pressure response. Mean arterial pressure was not permitted to rise to >120 mm Hg. Data points for mean arterial pressure and heart rate were taken when the blood pressure had stabilized at a given dose. The same protocol was repeated 6 to 8 weeks post partum in seven of the nine patients.

Data are presented as mean \pm SD. Statistical analysis was performed with an analysis of variance (two-way) for baroreflex sensitivity and a Wilcoxon signed rank test for vascular reactivity. A paired t test was performed to compare the maximal decrease in heart rate during phenylephrine infusion, both before and after birth (n = 7). A p < 0.05 was taken as the level of significance.

Results

Antepartum initial mean arterial pressure and heart rate averaged 77.4 ± 2.0 mm Hg (range, 70.0 to 87.0) and 81.6 ± 3.6 beats/min (range, 66.0 to 93.0), respectively. Postpartum mean arterial pressure averaged 83.7 ± 2.6 mm Hg (range, 77.5 to 94.0) and postpartum heart rate averaged 65.0 ± 5.0 beats/min (range, 54.0 to 87.0). The individual subject's maximal decrease in heart rate during phenylephrine infusion was 28.1 ± 3.3 beats/min (range, 15.0 to 40.0 beats/min) before birth and 18.4 ± 4.7 beats/min (range, 3.0 to 39.0) after birth (paired t test, p < 0.02).

The changes in heart rate and mean arterial pressure associated with phenylephrine infusion are shown in Fig. 1. The comparison of the slopes of these regression lines defines the corresponding difference in baroreflex sensitivity during pregnancy and 6 to 8 weeks post partum. Pregnancy is associated with an increase in baroreflex sensitivity to 0.9 beat/min/mm Hg, compared with 0.5 beat/min/mm Hg at 6 to 8 weeks post partum (analysis of variance, p < 0.007). Reflex sensitivity was unrelated to baseline heart rate.

The use of phenylephrine infusion on the same patients before and after birth allowed us to establish a dose-response relationship between dose of phenylephrine and increase in mean arterial pressure. A considerable amount of interindividual variation was found in the slopes of change in mean arterial pressure (millimeters of mercury) per unit dose (micrograms per kilogram per minute) of phenylephrine. Pregnancy was associated with attenuated responses to α-adrenergic stimulation, with a change of 21.5 ± 3.0 mm Hg per unit dose of phenylephrine, compared with $31.3 \pm 6.6 \text{ mm}$ Hg per unit dose (micrograms per kilogram per minute) of phenylephrine post partum (p < 0.05, Fig. 2).

To determine whether the slopes of the individual phenylephrine dose-blood pressure response relationship were influenced by the baroreflex sensitivity, the

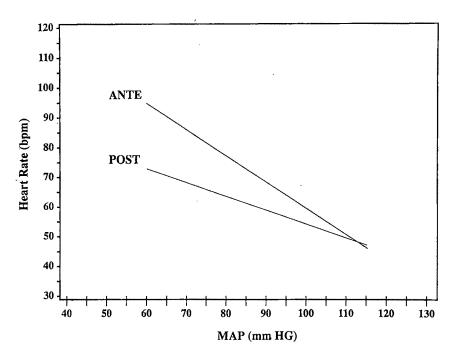

Fig. 1. Fitted curve of heart rate versus mean arterial pressure, including data from all patients. Slopes (ratio of change in heart rate produced per unit of change in mean arterial pressure) of two regression lines quantify baroreflex sensitivity (0.9 beat/min/mm Hg before birth [ANTE] vs 0.5 beat/min/mm Hg after birth [POST]; p < 0.007).

slopes of the change in mean arterial pressure (millimeters of mercury) per unit dose (micrograms per kilogram per minute) of phenylephrine were compared to ratio of change in heart rate produced per unit of change in mean arterial pressure. The relationship was defined by the following equation: y = -1.98x + 36.88; $r^2 = 0.33$, p = 0.0505. These data indicate that higher baroreflex sensitivity is associated with lower vascular responsiveness to α -adrenergic stimulation during pregnancy.

Comment

Many hemodynamic changes occur during pregnancy, including an increase in plasma volume and cardiac output that is accompanied by a fall in systemic vascular resistance and mean arterial pressure. Hence appropriate mechanisms to control the circulation and maintain the hemodynamic stability are required. The sinoaortic baroreflex represents the circulation's first defense against acute perturbations of systemic arterial pressure.

Seligman⁹ measured changes in pulse interval in response to elevation of blood pressure by phenylephrine or angiotensin and reported higher baroreflex sensitivity in normal pregnancy than in severe preeclampsia. However, he did not obtain measurements post partum. In our study the protocol was performed in the

same patient at term and again 6 to 8 weeks post partum. We found baroreflex sensitivity to be significantly higher in normal pregnancy at term than in the same subject post partum. This increased sensitivity may be of benefit during pregnancy in response to tilt and posture changes.

In studies with sheep, Magness and Rosenfeld¹¹ reported that at similar increases in mean arterial pressure the percent fall in cardiac output was greatest during pregnancy. The percent change in heart rate also was greatest in pregnant sheep during α -adrenergic receptor agonist stimulation.² These observations support the concept that normal pregnancy is associated with increased baroreflex sensitivity.

We assessed baroreflex sensitivity by means of the change in heart rate per unit change in mean arterial pressure. Higher baroreflex sensitivity was associated with a steeper slope, that is, a greater fall in heart rate per unit change in mean arterial pressure. Another characteristic of the sinoaortic baroreflex is the operating set point, that is, the blood pressure value that the baroreflex defends against any change. The lower baseline mean arterial pressure in pregnancy is perceived as normal. There is a shift away from the non-pregnant operating set point.

Our results indicated attenuated responses to α -adrenergic stimulation during pregnancy. These findings

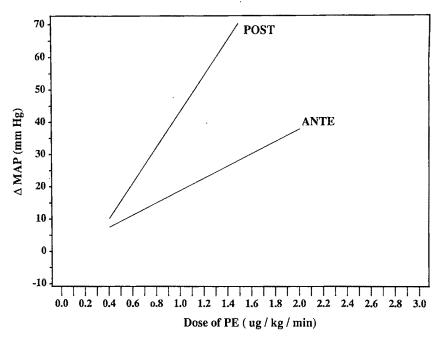

Fig. 2. Fitted curve of mean arterial pressure versus dose of phenylephrine infusion, including data from all patients. Slopes of change in mean arterial pressure (ΔMAP) (micrograms per kilogram per minute) of two regression lines quantify vascular responsiveness (21.5 ± 3.0 mm Hg per unit dose of phenylephrine before birth [ANTE] vs 31.3 ± 6.6 mm Hg per unit dose of phenylephrine after birth [POST] (p < 0.05).

are consistent with previous reports in animal models with infusions of norepinephrine, epinephrine, or phenylephrine.13-15 Similarly, the reduced pressor response to angiotensin II reported in pregnancy¹⁶ may be partly attributed to the increased baroreflex sensitivity. The phenomenon of reduced pressor responsiveness to angiotensin II in human pregnancy generally has been studied in relation to the dose of angiotensin II required to elicit a 20 mm Hg rise in blood pressure.16 Controversies exist about the exact mechanism by which attenuated pressor responses to angiotensin II appears to occur.17-19 It would be of interest to determine the extent to which baroreflex sensitivity correlates with the attenuated responsiveness to angiotensin in pregnant women.

Shepherd et al.20 explicitly demonstrated the relation between baroreflex sensitivity and vascular reactivity in the adult man. This association indicates the capacity of baroreflex function to buffer an increase in blood pressure. We also observed a relationship between these two parameters. However, we had a considerable amount of interindividual variation that could explain why our results did not reach a statistical significance. These data suggest that vascular reactivity is markedly attenuated in the presence of a sensitive sinoaortic baroreflex. Thus a patient with a lower baroreflex sensitivity would be more sensitive to vasoactive agents.

In summary, baroreflex sensitivity is increased in normal pregnancy at term, compared with that at 6 to 8 weeks post partum. The concomitant attenuated response to phenylephrine is probably in part related to this increased baroreflex sensitivity.

Changes in immunologic parameters in normal pregnancy and spontaneous abortion

Marjory A. MacLean, MB, ChB,^a Rhoda Wilson, PhD,^b John A. Thomson, MD,^b Srinivasan Krishnamurthy, MB, ChB,^a and James J. Walker, MB, ChB^a

Glasgow, Scotland

To study the immunologic characteristics of miscarriage, 40 nonpregnant control subjects, 40 primigravid women in the first trimester of pregnancy, and 18 patients admitted with a spontaneous abortion were investigated. The total white blood cell count was raised significantly in normal pregnancy and spontaneous abortion (p < 0.0005). The lymphocyte count was unchanged. The total T-cell number fell significantly in normal pregnancy and abortion (p < 0.01). No change was seen in the cytotoxic suppressor or helper/inducer T-cell numbers. The number of activated T cells fell significantly in both groups of patients (p < 0.0005). The response to mitogens was greatly increased in both normal patients and those with miscarriage. A marked rise in interleukin-2 receptor levels was noted in patients with spontaneous abortion (p < 0.005). The changes in white blood cell count, total T-cell number, activated T-cell number, and mitogen activity were thought to be a direct result of pregnancy. The rise in interleukin-2 receptor levels was seen only in the miscarriage group. Although it is not known if these changes are cause or effect, it would appear that immunologic abnormalities are associated with spontaneous abortion. (Am J Obstet Gynecol. 1991;165:890-5.)

Key words: Normal pregnancy, spontaneous abortion, immunologic changes

The fetus inherits genetic material from both parents; in spite of this, rejection usually does not occur. The mechanisms that prevent miscarriage are not fully understood. A change in the balance of maternal immunoregulatory cells toward greater suppression of the immune system could contribute to the immunoregulation of normal pregnancy. Approximately 15% of

pregnancies will end in miscarriage, usually in the first trimester of pregnancy. Once a fetal heart is seen on ultrasonographic examination, 95% to 98% of pregnancies will proceed successfully.1 Because fetal tissue is immunogenic, spontaneous abortion may have an immunologic cause.2 To investigate this possibility we have compared various immunologic parameters in three groups of women: nonpregnant women, normal pregnant women in the first trimester of pregnancy, and women admitted with noncontinuing pregnancy. The aim of this study was to assess whether any changes occur in T-cell subsets. B-cell function, mitogenic activity, and interleukin-2 (IL-2) receptor levels in pregnancy.

Methods

Forty nonpregnant, age-matched control subjects, 40 normal primigravid women in the first trimester of pregnancy, and 18 patients admitted with noncontinuing pregnancy were studied. The majority of the patients with noncontinuing pregnancy were recruited from the antenatal clinic after an ultrasonographic scan. In 12 women a diagnosis of blighted ovum was made; in five, the diagnosis was missed abortion; and one patient had an incomplete abortion. The parity ranged from 0 to 4, including two patients who had previously miscarried. The abortions all occurred in the first trimester of pregnancy. All patients gave informed consent before the investigation.

A total of 60 ml of blood was taken at the same time of day, and the following parameters measured: total white blood cell count (×109 cells/L), lymphocyte count (×10° cells/L), total T-cell number (×10° cells/L), helper/inducer T cells (×108 cells/L), cytotoxic/suppressor T cells (×10⁸ cells/L), activated T cells (×10⁸ cells/L), ratio of helper/inducer T cells to cytotoxic/suppressor T cells (×108 cells/L), mitogenic activity (tritiated thymidine), IL-2 receptors (U/ml), immunoglobulin G (ng/ml), and immunoglobulin M (ng/ml).

Peripheral blood lymphocytes. Heparinized blood was obtained from all control subjects and patients. The cells were then separated by density centrifugation with Ficoll-Hypaque³ and washed three times in minimal essential medium. The cells were then made to the required concentration in RPMI 1640 medium.

T-cell subset analysis. Samples were analyzed by a fluorescence-activated cell sorter (Becton Dickinson, Immunocytometry Systems, Mountain View, Calif.). This instrument is a flow cytometer that simultaneously measures electronic volume, wide-angle light scatter, and fluorescence signals from individual cells. The monoclonal antibodies used were supplied by Becton Dickinson. The CD3 monoclonal antibody reacts with total T cells; the CD4 monoclonal antibody, with helper/inducer T cells; the CD8 monoclonal antibody, with suppressor/cytotoxic T cells; and the Ia monoclonal antibody, with activated T cells. A differential white blood cell count was obtained for all patients, thus enabling the results to be expressed as absolute cell numbers.4

Response to mitogens. Peripheral blood lymphocytes were prepared in RPMI medium with 20% heatinactivated human serum (the same batch being used throughout) and made up to a concentration of either 1×10^6 cells per milliliter for phytohemagglutinin and concanavalin A or 2 × 106 cell per milliliter for pokeweed mitogen. All mitogens were used at optimal concentrations. Phytohemagglutinin, a helper T-cell mitogen, was used at a concentration of 10 µg/ml; concanavalin A, a suppressor T-cell mitogen, at a concentration of 100 µg/ml; and pokeweed mitogen, a B- and T-cell mitogen, at 0.2 μg/ml. All cultures were done in triplicate, and the cells were grown for 96 hours at 37° C, 95% humidity, and 5% carbon dioxide. Tritiated thymidine (1 µCi per well) was added for the last 4 hours of the incubation, and the cells harvested with a Dynatech cell harvester (Dynatech, Billinghurst, Sussex). The cells were then washed onto glass fiber disks with water and then fixed with 5% trichloroacetic acid and dried with methanol before the uptake of tritiated thymidine by peripheral blood lymphocytes.⁵ The interassay variability for the mitogenic assay was 7.2%. No positive control was used in the assay as the response to stimulation with pokeweed mitogen, phytohemagglutinin, or concanavalin A was sufficiently great, compared with that of controls (Fig. 1), that this was found not to be necessary.

IL-2 receptors. IL-2 receptors mediate the action of IL-2, an immune system growth hormone. Normal resting T and B cells do not display significant numbers of these receptors on their cell surfaces, but when these cells are stimulated by a challenge to the immune system, the number of IL-2 receptors on the plasma membranes of the cells increases and a form of the IL-2 receptor protein is released into the surrounding fluid by the activated cells. It is this soluble protein that is measured with a sandwich enzyme immunoassay kit (Laboratory Impex. Ltd., Teddington, Middlesex). The assay involves coating an anti-IL-2 receptor monoclonal antibody onto the wells of a microtiter plate. Soluble IL-2 receptor present in the sample or standard will then bind to the antibody on the wells. An enzymeconjugated anti-IL-2 receptor monoclonal antibody directed against a second epitope on the IL-2 receptor molecule is then added. This binds to the IL-2 receptor captured by the first antibody, thus completing the sandwich. Any unbound, enzyme-conjugated IL-2 receptor is removed by washing. A substrate solution is then added and the colored product formed is pro-

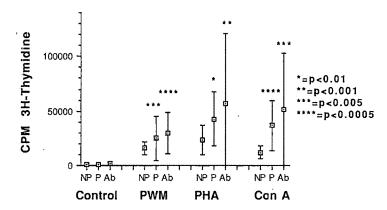

Fig. 1. Response of T cells in nonpregnant women (n = 40), normal pregnant women (n = 40), and patients with spontaneous abortion (n = 18) to control and three mitogens: pokewood mitogen (PWM), phytohemagglutinin (PHA), and concanavalin A $(Con\ A)$. Results expressed as counts per minute of tritiated thymidine uptake, showing $\pm 1\ SD$ by horizontal lines. Statistical significance is marked above each column. NP, Nonpregnant; P, normal pregnant; Ab, spontaneous abortion.

portional to the amount of IL-2 receptor present in the sample. This assay has an interassay variation of 3.7% and an intraassay variation of 11%.

B-cell studies. B-cell studies were performed as described previously. Briefly, peripheral blood lymphocytes were made to a concentration of 1×10^6 cells per milliliter in RPMI medium with 20% fetal calf serum (the same batch being used throughout the study). The amount of immunoglobulins G and M released from the cells into the culture medium was measured with an enzyme-linked immunosorbent assay.

Results are given as mean ± 1 SD. Statistical analyses were performed by means of a one-way analysis of variance.

Results

The results of the changes in T lymphocytes are shown in Table I. Although the total white blood cell count was significantly increased in normal pregnancy and in spontaneous abortion (p < 0.0005) compared with the nonpregnant controls, the lymphocyte count was unchanged. The total T-cell number was significantly reduced in the normal pregnant and abortion groups. There was no significant change in the numbers of helper/inducer or cytotoxic/suppressor T cells compared with those of nonpregnant women. The number of activated T cells was significantly lower in both groups (p < 0.0005). The ratio of helper/inducer T cells to cytototoxic/suppressor T cells was unchanged.

The changes in mitogenic activity are shown in Fig. 1. A significant rise in mitogenic activity to pokeweed mitogen, phytohemagglutinin, and concanavalin A was seen in both groups of patients when compared with nonpregnant control subjects. In the absence of mitogen there was no rise in T-cell activity.

There was no significant change in IL-2 receptor

levels in the normal pregnant group (Table II), but a significant rise (p < 0.001) was seen in the spontaneous abortion group.

The amount of immunoglobulin produced by mitogen-stimulated peripheral blood lymphocytes is shown in Table II. Immunoglobulin G and M production was significantly raised in the first trimester of normal pregnancy and in women with spontaneous abortion, although the latter was less significant because of the wide variation as shown by the large standard deviation.

Comment

For a pregnancy to continue the mother must tolerate fetal tissue that is foreign to her immune system. There are thought to be various protective mechanisms preventing immune attack.⁷

The two major cells of the immune system are T and B lymphocytes. While maturing in the thymic medulla, the T cells develop a receptor for antigens. Those destined to have cytotoxic/suppressor functions resemble the class I major histocompatibility complex antigens, whereas those with helper/inducer functions resemble class II major histocompatibility complex antigens. Foreign antigens will be recognized only if there is a major histocompatibility complex molecule on the cell surface that can be recognized by the T cells.⁸

A certain degree of genetic disparity between mother and fetus has been reported to benefit the developing pregnancy.⁹ A poorer outcome has been seen where there is excess antigen sharing in couples at the major histocompatibility complex, because this prevents recognition of the pregnancy as foreign and a helpful immune response is not produced.¹⁰ Sharing of minor histocompatibility or trophoblast-lymphocyte crossreactive antigen may be significant but is poorly understood.¹¹ Maternal recognition of incompatible

trophoblast-lymphocyte cross-reactive antigens on trophoblast could lead to the production of protective factors (e.g., blocking antibodies) beneficial to pregnancy.¹²

In our study the rise in total white blood cell count that was found in the pregnant women and patients with spontaneous abortion is a well-known effect of pregnancy, primarily caused by a neutrophilia.13

We found that alterations in the number of total and activated T cells were associated with both normal pregnancy and spontaneous abortion. This would appear to be an effect of pregnancy. Various changes in T-cell subset patterns have previously been reported. Sumiyoshi et al.14 found the number of helper/inducer T cells to be decreased and the number of cytotoxic/suppressor T cells to be increased in normal pregnancy. Threatened abortion was associated with a reduction in cytotoxic/suppressor T cells. In contrast, Vanderbeeken et al. 15 found a fall in the percentage of total Tcell numbers as a result of a decrease in helper/inducer T cells. The ratio of helper/inducer to cytotoxic/suppressor T cells also was decreased. Moore et al. 16 also found a decrease in helper/inducer T cells, although this was not statistically significant. The discrepancy between these earlier studies and this one may be due to expression of the results as percentages rather than absolute numbers. Alternatively, it may be related to the methods used or variations in patient populations.

We also found a fall in activated T-cell number, but

this was not the observation made by Vanderbeeken et al.,15 who found no change in the Ia antibody number in normal pregnancy.

To investigate the sensitivity of T cells, their response to pokeweed mitogen, phytohemagglutinin, and concanavalin A was studied. Like Sumiyoshi et al.,14 we found an increased response to mitogenic stimulation by lymphocytes of women with spontaneous abortion when compared with that of healthy pregnant women. However, unlike these authors we found the response in healthy women to be elevated when compared with that of control subjects, although it was significantly lower than the results found in spontaneous abortion. The reasons for this discrepancy are not clear at present. No increase was observed in the absence of mitogenic stimulation, It is possible that in normal pregnancy some cell stimulator is produced, and in spontaneous abortion this may be produced in excess.

One of the first events in the activation and release of T lymphocytes is the expression of IL-2 receptors on the surface that are subsequently released in a soluble form and the secretion of a lymphokine, IL-2, that exerts its biologic effects by interacting with the receptors.17 The receptor release is maximal around 6 days after T-cell challenge.18 It is known that IL-2 receptor levels may increase in renal graft rejection,19 and the prognosis of certain tumors, e.g., non-Hodgkin's lymphoma, may be monitored by IL-2 receptor levels.20 In this study no rise in IL-2 receptor levels was seen in the normal pregnant group; however, a significant rise was found in the group with spontaneous abortion. In a study performed by Stone et al.,21 three groups of women were studied after embryo or gamete transfer: those who failed to conceive, those who had a continuing pregnancy, and those who underwent spontaneous abortion. Blood was collected before transfer and on days 7 and 14 after embryo or gamete transfer, before full implantation would have occurred. At these times no significant differences in IL-2 receptor levels were found among the groups. In our study the changes were observed after the first missed menstrual period, during the first trimester of pregnancy, with ultrasonographic evidence of an implantation. The rise in IL-2 receptor levels indicates activation of the immune system and may reflect an immunologic rejection of the fetus as a cause of spontaneous abortion. It would have been interesting to see serial changes in the patients of Stone et al. who proceeded to miscarry and whether immunologic changes occurred at a later time.

It is not clear if the raised IL-2 receptor levels that we found in the patients with spontaneous abortion are causative or a result of a process that has become inevitable. However, monitoring of IL-2 receptor levels in patients with a threatened miscarriage may lead to a more accurate prediction of the outcome of the pregnancy.

Immunoglobulin production from peripheral blood lymphocytes was elevated in normal pregnancy and spontaneous abortion (Table II). Whether this is due to an increase in B-cell numbers or whether it is the result of increased production is not clear at present. There have been results in the literature of increased B-cell numbers occurring in normal pregnancy²²; however, these may have been inaccurate because the earlier tests interacted with monocytes, as well as with B cells.

These results suggest that, in addition to activation of T cells (as reflected by elevated IL-2 receptor levels), there is also activation of B cells in some cases of spontaneous abortion. At present it cannot be determined if these events occur singly or whether activation of one system leads to activation of the other. It would be unlikely that all cases of spontaneous abortion are caused by immunologic abnormalities. This is suggested by the wide range of results in our abortion group, with some results grossly abnormal and others within the normal range. Abnormality of the conceptus is another likely cause; however, chromosomal analysis of products of conception were not carried out in our study as it is only available for patients with a history of recurrent abortion. The possibility of altering the outcome of the pregnancy if an immunologic abnormality is identified may have practical implications.

Treatment of recurrent abortion with progesterone or human chorionic gonadotropin has previously been tried and various results have been noted.²³ Any treatment would have to commence as early as possible to allow the maximum benefit to the pregnancy.

Further studies looking at serial changes in normal pregnancy and changes in patients with a history of recurrent abortion being treated with human chorionic gonadotropin are currently under way in our unit. It is hoped that these will help to clarify some of our initial findings.

High plasma cellular fibronectin levels correlate with biochemical and clinical features of preeclampsia but cannot be attributed to hypertension alone

Robert N. Taylor, MD, PhD,^a William R. Crombleholme, MD,^a Steven A. Friedman, MD,^a Lynn A. Jones, MA,^b David C. Casal, PhD,^b and James M. Roberts, MD^a

San Francisco and Sunnyvale, California

Current concepts of the pathogenesis of preeclampsia involve the generalized dysfunction of maternal vascular endothelial cells. We measured the endothelial isoform of fibronectin as a marker of endothelial cell injury throughout pregnancy in a prospective, case-control study. Nineteen women met strict criteria for the diagnosis of preeclampsia. Nineteen normal pregnant women, and 19 women with gestational hypertension but without other stigmata of preeclampsia (transient hypertension) were selected from the same cohort and matched according to race, age, nulliparity, and gestational age at delivery. Plasma levels of cellular fibronectin were significantly elevated in women meeting strict clinical and biochemical criteria for preeclampsia but not in women with normal pregnancies or transient hypertension. Moderate but significant elevations in mean levels were found in the second trimester in women destined to have preeclampsia, as compared with matched normal and transient hypertension groups ($\rho < 0.05$). The results indicate that elevated plasma levels of cellular fibronectin are not simply the result of increased blood pressure but reflect a maternal insult specific to the syndrome of preeclampsia. Elevation of the mean concentration during the midtrimester is consistent with the hypothesis that endothelial cell injury is a specific lesion that occurs early in the course of preeclampsia, before clinical signs and symptoms. (Am J Obstet Gynecol 1991;165:895-901.)

Preeclampsia is a prevalent, pregnancy-specific disorder of unknown etiology and pathogenesis. It is defined as a syndrome manifested by gestational hypertension, excessive proteinuria, and generalized edema. Although increased blood pressure is normally the first manifestation noted clinically, recent studies suggest that hypertension per se is a less important pathogenetic feature of preeclampsia than are vasospasm and ischemia, which appear to mediate the significant maternal and perinatal morbidity associated with this syn-

drome. Moreover, transient hypertension, another hypertensive condition of pregnancy that is not associated with proteinuria, also does not carry the perinatal or maternal morbidity of preeclampsia. Unfortunately, it is often difficult to distinguish the early stages of these two conditions by clinical findings.

Because proteinuria, edema, activation of the coagulation cascade, and increased sensitivity to vasopressor agents may all be explained by endothelial dysfunction, we proposed that maternal vascular endothelial cell injury is a central and early feature in the development of the preeclamptic syndrome.24 This report describes our examination of cellular fibronectin, the endothelial cell-derived isoform of fibronectin, a plasma marker of endothelial cell injury, in the three trimesters of pregnancy. Fibronectins are a family of ubiquitous, highmolecular-weight extracellular matrix glycoproteins involved in a variety of fundamental tissue interactions, including cell adhesion and migration.5 These proteins are shed into the circulation, where they constitute a significant fraction of total plasma protein. The predominant isoform of circulating fibronectin is derived from hepatocytes.⁵ An isoform of fibronectin associated with endothelial cells and endothelial cell matrix in vivo, cellular fibronectin, is generated by alternative posttranscriptional processing of the fibronectin gene product. 5, 6 Cellular fibronectin is a minor component of circulating fibronectin, constituting <5% of the total plasma pool. The endothelium-derived protein bears two extra domains not found on the abundant hepatocyte-derived fibronectin.6 To assess the extent of maternal vascular endothelial cell injury during pregnancy, we have quantified circulating cellular fibronectin with a monoclonal antibody that selectively recognizes a conformational epitope near the extra domain-B (ED-B) region of endothelial-type cellular fibronectin.

We report that plasma cellular fibronectin concentrations are significantly elevated as early as the second trimester in women destined to have preeclampsia but not in women who have normal pregnancies or transient hypertension.

Material and methods

All pregnant women registering for prenatal care at Moffitt-Long Hospital of the University of California, San Francisco, and at San Francisco General Hospital since July 1988 have been invited to participate in a prospective study of preeclampsia. Blood samples were obtained serially throughout pregnancy at routine venipuncture. Such routine testing included the usual prenatal laboratory tests (first trimester), maternal α -fetoprotein screening (second trimester), glucose screening (late second or early third trimester), repeat hemoglobin and hematocrit screening (mid third trimester), and peripartum testing at labor and delivery

(late third trimester). Participating patients gave written informed consent for the sampling on a form approved by the University's Committee on Human Research. The blood samples were collected in sterile tubes containing ethylenediaminetetraacetate (EDTA) as an anticoagulant. The plasma was fractionated, and aliquots were coded and frozen at -70° C for later analysis. In samples collected at term, plasma specimens were obtained before intravenous hydration, magnesium sulfate infusion, or antihypertensive medication and thus were unaffected by differences in clinical management or therapy of parturients thought to have hypertensive conditions.

The women studied in this cohort were followed up throughout pregnancy, labor, delivery and for ≥12 weeks post partum with serial clinical observations, including measurements of blood pressure and proteinuria. Blood pressures were measured in the prenatal and postdelivery follow-up clinics with patients in an upright, seated position, with the first and fifth Korotkoff sounds. Intrapartum blood pressure results were obtained with the patient in the recumbent position with slight left lateral tilt and reflect the average of at least four measurements made before administration of medication or initiation of epidural anesthetic. At the completion of the final postpartum evaluation (≥12 weeks after delivery), the clinical and laboratory data were reviewed by a jury of clinical investigators who were blinded to the results of the plasma cellular fibronectin determinations. Each patient was assigned to one of three study groups: preeclampsia, normal, or transient hypertension. Patients with preeclampsia fulfilled criteria recommended by Chesley,7 namely, nulliparity, absence of a history of hypertension before pregnancy, increase in diastolic pressure of 15 mm Hg or systolic pressure of 30 mm Hg compared with blood pressures obtained before 20 gestational weeks, proteinuria ≥0.5 gm/24 hours or ≥30 mg/dl in a catheterized specimen, hyperuricemia >5.5 mg/dl (or 1 SD greater than the normal mean value before term8), and return to normal blood pressure and resolution of proteinuria by 12 weeks post partum. Patients with transient hypertension were defined by nulliparity, absence of hypertension before pregnancy, blood pressure criteria as defined above for preeclampsia but without proteinuria and hyperuricemia, and return to normal blood pressure within 12 weeks of delivery. Normal controls were selected from the same cohort of nulliparous parturients, in whom neither hypertension, proteinuria, nor hyperuricemia was observed throughout the study period. Criteria that resulted in the exclusion of patients from this study were the identification of any chronic metabolic disease, evidence of illicit drug use by urine toxicology screens, or the failure of elevated blood pressure, hyperuricemia, or proteinuria to

Table I. Demographic, clinical, and biochemical features of term pregnancies

	Preeclampsia (n = 19)	Normal (n = 19)	$Transient \\ hypertension \\ (n = 19)$
Maternal age at delivery (yr)	25 ± 2	29 ± 1	29 ± 2
Gestational age at delivery (wk)	39 ± 1	40 ± 1	39 ± 1
Serum creatinine (mg/dl)	0.8 ± 0.1	0.7 ± 0.1	0.8 ± 0.1
Hematocrit (vol/vol, %)	36 ± 1	37 ± 1	37 ± 1
Placental weight (gm)	694 ± 26	680 ± 22	630 ± 37
Infant weight (gm)	3202 ± 121	3536 ± 105	$3124 \pm 175*$
Serum uric acid (mg/dl)	$7.0 \pm 0.3 \dagger$	3.9 ± 0.3	5.1 ± 0.6
Mean arterial pressure (mm Hg)	$108 \pm 3*$	77 ± 2	109 ± 4*
Platelet count (×1000/µl)	$223 \pm 20 \ddagger$	255 ± 19	277 ± 17
Plasma cellular fibronectin (µg/ml)	$9.5 \pm 1.2 \dagger$	3.5 ± 0.4	3.7 ± 0.7

These data (expressed as mean ± SE) were analyzed by analysis of variance with Fisher's post hoc comparisons between groups.

resolve within 12 weeks of delivery. Patients from each group were matched for race, age, and gestational age at delivery.

Plasma cellular fibronectin levels were determined by a specific enzyme-linked immunosorbent assay (ELISA) technique with the monoclonal antibody A134, which recognizes a conformational epitope near the ED-B region of cellular fibronectin (unpublished observations). Aliquots of each freshly thawed plasma sample were diluted 1:20 in sample buffer and assayed in duplicate with an intraassay coefficient of variation of 6%, an interassay coefficient of variation of 9%, and a sensitivity of $<0.1 \mu g/ml$. This assay was developed and performed at Adeza Biomedical. Plasma samples were collected prospectively throughout pregnancy as described above; however, first- and second-trimester specimens were not available for all patients. When possible, at least one sample from each trimester was obtained. When several samples from a single trimester were available for a given patient, an average level for that trimester was calculated (<13 menstrual weeks, first trimester; 13 to 26 weeks, second trimester, ≥27 weeks, third trimester). The mean (±SE) plasma cellular fibronectin concentration in 50 consecutive specimens obtained from an independent group of normal pregnant women was $3.8 \pm 0.1 \,\mu\text{g/ml}$ in the same laboratory.

Confirmation of the specificity of the A134 antibody was afforded with a combination of isoelectric focusing, membrane transfer, and ligand blotting. Briefly, protein G-purified A134 monoclonal antibodies were electrofocused at 8 mA constant current in polyacrylamide gels containing a mixture of ampholines (pH 3 to 10 and pH 5 to 7, 1:4, vol/vol), 1% NP-40, and 10% sorbitol. The proteins were transferred to nitrocellulose membranes (Schleicher and Schuell, Keene, N.H.) and

replicate blots were incubated with 10 μg/ml of either cellular fibronectin isolated from human amniotic fluid9 or plasma fibronectin (Boehringer-Mannheim, Indianapolis). A polyclonal rabbit antihuman total fibronectin antiserum (A120, Adeza Biomedical, which recognizes a common determinant in all forms of human fibronectin) conjugated to alkaline phosphatase was subsequently incubated with the membrane filters in the presence of substrate (5-bromo-4-chloro-3-indolyl phosphate, Sigma Chemical Co., St. Louis) to identify cellular fibronectin-specific bands on the immunoblots.

Experiments to document the expression of cellular fibronectin by human endothelial cells were performed with primary human umbilical vein endothelial cell cultures as previously described.2 In some experiments matched cultures of human umbilical vein endothelial cells were exposed to bacterial endotoxin (lipopolysaccharide from Escherichia coli serotype 055:B5, 1 µg/ml, Sigma) for 24 hours, to provide a model of endothelial cell activation or injury. The human umbilical vein endothelial cells were washed with phosphate-buffered saline solution (pH 7.4) and lysed in a hypotonic solution of 10 mmol/L Tris, 1 mmol/L EDTA (pH 7.4) with repeated tituration through a 22-gauge syringe. The cell lysates were assayed for cellular fibronectin content by ELISA and total cellular protein was determined by the Bradford method.11

Statistical tests performed in these studies included descriptive, multiple comparison and correlation analyses of clinical and biochemical parameters among preeclampsia, normal, and transient hypertension groups. Results of this study are reported as the group mean \pm SE. Analysis of variance with Fisher's multiple comparison post hoc tests were used to assess differences among the three groups of patients. In some cases

Transient hypertension	86 ± 2	84 ± 1	$95 \pm 2 †$
Hemoglobin (gm/dl)			
Preeclampsia	ND	11.9 ± 0.3	12.2 ± 0.3
Normal	ND	12.0 ± 0.4	12.8 ± 0.3
Transient hypertension	ND	12.1 ± 0.3	12.7 ± 0.4

These data (expressed as mean \pm SE) were analyzed within each trimester by analysis of variance with Fisher's post hoc comparisons between groups. ND, Not determined.

simple correlation analyses were performed. When longitudinal differences throughout pregnancy were assessed, clinical and biochemical data for each patient were averaged to yield a single value for each trimester of pregnancy. Prepartum cellular fibronectin concentrations were analyzed with diagnostic group and the presence of labor as main effects in a two-way analysis of variance to examine the possible interaction of labor on cellular fibronectin levels. Tests with p < 0.05 were accepted as significantly different.

Results

Nineteen women met the stringent requirements for the diagnosis of preeclampsia. From the same cohort, 19 normal controls and 19 women with transient hypertension were selected and matched to the preeclamptic patients. The results in Table I show the mean ± SE values of the clinical and biochemical findings in the late third trimester, immediately before delivery. As expected from the criteria used to define the three groups, blood pressures were significantly elevated in the preeclampsia and transient hypertension groups relative to normal controls. Similarly, the mean proteinuria and uric acid levels were greater in preeclamptic pregnancies than in either of the remaining groups (p < 0.05). By contrast, maternal age, gestational age, hematocrit, creatinine concentration, and placental weights were not different among the three groups in this patient population. The mean platelet count in the preeclampsia group was slightly, but significantly, less than that of the transient hypertension group. The mean infant weight in transient hypertension pregnancies was statistically less than that in normal pregnancies (Table I). The interval between initial presumptive diagnosis and onset of labor was $3.4\,\pm\,1.2$ days and 10.4 ± 2.9 days for the preeclampsia and

transient hypertension groups, respectively. The preeclampsia group manifested diagnostic hypertension 6.9 ± 1.7 days before the onset of labor. As discussed previously, however, assignment of the final diagnoses was made after 12 weeks post partum.

The results of the plasma cellular fibronectin analyses, shown in Fig. 1, demonstrated that mean cellular fibronectin levels were significantly greater in preeclampsia (9.5 \pm 1.2 μ g/ml) than in matched normal $(3.5 \pm 0.4 \,\mu\text{g/ml})$ or transient hypertension $(3.7 \pm 0.7 \,\mu\text{g/ml})$ $\mu g/ml$) pregnancies at term (n = 57, p < 0.05). Of these patients, 61% (23/57) were in labor at the time of the final prepartum blood sample. Neither the presence nor absence of labor nor the interaction between the study groups and labor significantly affected the cellular fibronectin concentration (F = 0.87, p > 0.42, two-way analysis of variance, n = 57). When cellular fibronectin concentrations were analyzed independently of the patient groups, they were found to correlate positively with concentrations of urine protein, serum uric acid and creatinine (r > 0.56, p < 0.001) and negatively with platelet count and infant weight (r > 0.28, p < 0.05).

The mean plasma cellular fibronectin levels of each patient group were compared during each of the three trimesters of pregnancy (Fig. 2). While we found no statistical differences among patients in the first trimester, average levels were elevated by the second trimester in women destined to have preeclampsia, relative to matched normal and transient hypertension groups (p < 0.05). By contrast, the traditional clinical parameter of blood pressure achieved diagnostically significant levels only during the third trimester (Table II). The hemoglobin concentrations in these patients were indistinguishable among the three groups in both the second and third trimesters (Table II). In the imme-

^{*}Value differs significantly from normal and transient hypertension groups (p < 0.05).

[†]Value differs significantly from normal group (p < 0.05).

diate postpartum period (≤48 hours after delivery) cellular fibronectin levels tended to decrease but remained statistically higher in the preeclamptic group (6.2 \pm $0.4, 3.6 \pm 0.4, \text{ and } 3.2 \pm 0.7 \,\mu\text{g/ml}, n = 56, \text{ for pre-}$ eclampsia, normal, and transient hypertension groups, respectively).

The specificity of A134 was demonstrated by isoelectric focusing of the monoclonal antibodies and transferring these to nitrocellulose filters. With the A134 immunoglobulin fixed to nitrocellulose, the monoclonal antibody binds a cellular isoform of fibronectin present in amniotic fluid but not in plasma fibronectin (Fig. 3). Identical data were obtained with these and other purified preparations of cellular fibronectin and plasma fibronectin when A134 immunoglobulin was fixed to microtiter plates with the enzyme-linked immunosorbent assay format (data not shown).

To ascertain that the cellular fibronectin epitope recognized by the monoclonal antibody A134 was indeed expressed by human endothelium, cultures of normal human umbilical vein endothelial cells were grown to confluence in media reconstituted with 20% fetal calf serum, washed, lysed, and assayed for cellular fibronectin production by enzyme-linked immunosorbent assay. Neither fetal calf serum containing media nor lysis buffer had detectable cellular fibronectin. Human umbilical vein endothelial cells cultured under normal conditions contained 0.46 µg cellular fibronectin per milligram cellular protein. In identical cells exposed to 1 μg/ml bacterial endotoxin in vitro the concentration increased to 0.90 µg cellular fibronectin per milligram cellular protein.

Comment

Several clinical and biochemical findings support the hypothesis that maternal vascular endothelial cell injury plays an important role in the pathogenesis of the preeclampsia syndrome. The increased rate of disappearance of circulating Evans blue dye, 12 elevations of factor VIII antigen,13 decreased levels of prostacyclin,14 and the pathognomonic renal biopsy findings15 in these women suggest vascular endothelial cell dysfunction. Studies from our own laboratory have provided both direct² and indirect³ evidence of endothelial cell injury in this condition. Previous studies, using total¹⁶ and cellular17 plasma fibronectin as markers, demonstrated significant differences between normal and preeclamptic pregnancies.

This investigation was designed to compare the plasma concentrations of cellular fibronectin among normal pregnant women, patients with unambiguous preeclampsia, and pregnant women with transient hypertension as defined under the American College of Obstetricians and Gynecologists' classification of hypertensive disorders in pregnancy18 and in a recent re-

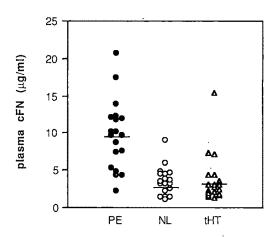

Fig. 1. Distribution of plasma cellular fibronectin (cFN) levels in preeclampsia (PE, •), normal (NL, o), and transient hypertension (tHT, Δ) pregnancy groups was determined at term. Nineteen patients with preeclampsia and 19 patients each in the normal and transient hypertension groups were studied (some overlapping values are not resolved in scattergram). Horizontal lines indicate mean cellular fibronectin concentration of each group.

vision of these criteria.19 The latter diagnosis, which currently can be made only retrospectively, tends to recur in subsequent pregnancies and is a harbinger of eventual essential hypertension. Previous studies suggest that it is not associated with increased maternal or fetal morbidity.1 In our study the mean interval between the first observation of diagnostically elevated blood pressure and the onset of labor was similar in preeclampsia (6.9 days) and transient hypertension (10.4 days) groups (p > 0.22), although on average complete diagnostic criteria for preeclampsia were not met until 3.4 days before labor. This observation reflects the aggressive management of preeclamptic pregnancies in our institutions once the diagnosis has been established. Additionally, however, the longer interval in transient hypertensive pregnancies indicates that these women differ remarkably from their normal peers, with substantial blood pressure elevation before the onset of uterine contractions.

In the second and third trimesters of pregnancy, cellular fibronectin levels were significantly greater in patients ultimately classified as having preeclampsia, relative to matched normal and transient hypertension pregnancies in the same cohort. That this finding was not noted in pregnancies complicated by transient hypertension indicates that elevated blood pressure per se is not responsible for the increase in plasma cellular fibronectin levels of preeclampsia. Significant elevations were detectable as early as the second trimester in women destined to have preeclampsia, suggesting that maternal vascular endothelial cell injury, as detected by the release of an endothelial isoform of fi-

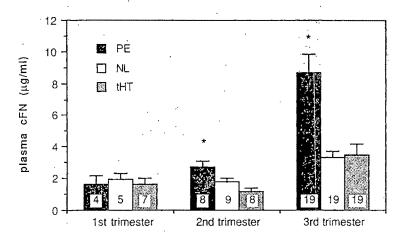

Fig. 2. Prospective analysis of plasma cellular fibronectin levels was performed throughout pregnancy. Average concentrations were determined for each trimester in the same preeclampsia (PE, dark histograms), normal (NL, open histograms), and transient hypertension (tHT, stippled histograms) groups. Cellular fibronectin levels in plasma from women destined to have preeclampsia were statistically greater in second- and third-trimester samples relative to the other two groups (p < 0.05, analysis of variance with Fisher's test). Values at base of each histogram indicate number of patients assessed at that gestational interval.

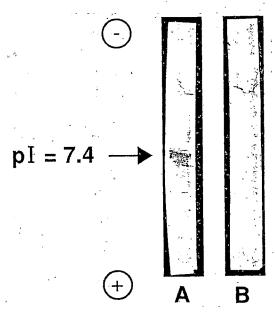

Fig. 3. Electrofocusing—Western ligand blot of A134 monoclonal antibody. Affinity-purified A134 monoclonal antibodies underwent electrofocusing and were transferred to nitrocellulose as described in Material and methods. Filters were incubated with either amniotic fluid fibronectin (lane A) or plasma fibronectin (lane B), and polyclonal antifibronectin antiserum (A120, conjugated to alkaline phosphatase) was added. Deposition of a colored reaction product demonstrated that A134, which was focused at isoelectric point = 7.4, recognizes a cellular isoform of fibronectin in amniotic fluid (lane A), but the antibody failed to bind plasma fibronectin (lane B).

bronectin, is an early and specific phenomenon in the pathogenesis of preeclampsia.^{2,20} Thus one of the most important findings of this study is that a fundamental difference exists between the pathophysiologic char-

acteristics of transient hypertension and that of preeclampsia. Chesley,⁷ among others, has long admonished against including patients with nonproteinuric hypertension in clinical investigations of preeclampsia. This precaution may be particularly relevant to studies from some European and British centers that, according to the diagnostic criteria proposed by Nelson,²¹ do not require proteinuria for the diagnosis of preeclampsia.

As our cellular fibronectin data are presented as circulating concentrations (micrograms per milliliter), a possible explanation for the apparent increase in pre-eclamptic women could be secondary to the reduced plasma volume reported in this condition. In this study no statistical differences in hemoglobin concentrations or hematocrit levels among the three groups were detected, indicating that cellular fibronectin levels expressed as a specific activity (e.g., micrograms cellular fibronectin per gram hemoglobin) also are elevated significantly in the second and third trimesters in women destined to have preeclampsia. Thus hemoconcentration per se cannot explain the observed increase in cellular fibronectin concentration.

An unanswered question is whether cellular fibronectin quantification may provide a marker as a midtrimester screening test for preeclampsia. To date, the rollover test,²² response to angiotensin II infusion,²³ and factor VIII antigen concentrations¹³ have been suggested as predictive tests, yet none has seen widespread utility. Lazarchick et al.¹⁶ reported that elevations in total fibronectin may be predictive in women destined to have preeclampsia. As plasma total fibronectin primarily reflects release of hepatic fibronectin, measurement of the endothelial cell isoform might provide an earlier and more specific marker of preeclampsia, as

demonstrated recently by Lockwood and Peters. 17 However, the overlap of second-trimester values in these preliminary studies suggests that cellular fibronectin is unlikely to be clinically useful as a cross-sectional predictor of preeclampsia.

We are in the process of extending this prospective, blinded analysis to ascertain whether longitudinal assessment of cellular fibronectin in individual patients can predict the 5% to 10% of pregnant women expected to have preeclampsia.1 Previous trials of high-risk patients suggest that tests with positive predictive values of 20% to 40% would identify appropriate candidates for prophylactic, low-dose aspirin therapy.24 Moreover, with increasing evidence that progressive maternal endothelial cell dysfunction is responsible for many of the pathophysiologic findings of the preeclamptic syndrome, we are searching for the circulating factor(s) that incites this process in vivo. Once such a factor(s) is identified, rational and specific therapy designed to reverse the pathologic processes involved in preeclampsia should be forthcoming.

We thank Jean Perry, RN, MS, Patricia Payne, and Sheri Rosenberg for careful assistance with data collection; Russell Laros, MD, and Patricia Robertson, MD, for review and analysis of clinical records; Subba Rao Gunupudi, PhD, for the A134 immunoblot data; Cindy Voytek for assistance with the figures; and Alan Goldfien, MD, for his helpful comments.

The effect of maternal hemodynamics on fetal growth in hypertensive pregnancies

Thomas R. Easterling, MD, Thomas J. Benedetti, MD, Karen C. Carlson, RN, Debra A. Brateng, RN, Judy Wilson, RN, and Barbara S. Schmucker, RN Seattle, Washington

Seventy-six pregnancies in which hypertension complicated pregnancy before 28 weeks' gestation were studied. In 36, hemodynamics were characterized by increased cardiac output and low vascular resistance; in 32, hemodynamics were characterized by high resistance; in eight hemodynamics crossed over from high output to high resistance during pregnancy. High-resistance hypertension was associated with a mean birth weight 1058 gm less than that in the low-resistance group (p=0.001). The reduction in birth weight was due to a 4-week difference in gestational age (p=0.001) and lower percentile weights for gestational age, 19th versus 39th (p=0.005). Infants in the crossover group had low percentile weights and a high rate of intrauterine fetal death. (AM J OBSTET GYNECOL 1991;165:902-6.)

Key words: Hypertension, intrauterine growth retardation, cardiac output

Maternal hypertension is associated with increased risk of compromised fetal growth and intrauterine death. However, adverse fetal effects are not uniform; some pregnancies complicated by hypertension severe enough to require delivery for maternal indications produce infants that are normally grown without evidence of uteroplacental insufficiency. Over the past 6 years we have routinely measured the cardiac output noninvasively in most hypertensive pregnancies. Clinical experience has led us to hypothesize that the incidence of impaired fetal growth in hypertensive pregnancies is related to the individual character of maternal hemodynamics. Specifically, high-resistance hypertension seems to be associated with an increased incidence of intrauterine growth retardation while high cardiac output, low-resistance hypertension is frequently associated with normal fetal growth. The following retrospective study was designed to test this hypothesis.

Material and methods

We reviewed our hemodynamic data to identify pregnancies where hypertension was diagnosed at ≤28 weeks of gestation. Hypertension was defined as a diastolic pressure of 90 mm Hg on two occasions 6 hours apart. Screening blood pressures were measured by

auscultation and the fifth Korotkov sound. We chose to study women whose hypertension was evident early in pregnancy so that potential fetal effects would be maximized. We hypothesized that fetal effects would be related to the pattern of maternal hemodynamics; therefore we did not analyze the data on the basis of the presence or absence of chronic hypertension or proteinuria. Given the high rate of underlying maternal disease associated with early hypertension in pregnancy, we thought that these characterizations would frequently be inaccurate.

Cardiac output was measured by Doppler technique with the woman in a left lateral semirecumbent position. We have previously validated the accuracy and reproducibility of this technique in pregnancy.^{2,3} Blood pressure was measured by automated cuff. Mean arterial pressure and total peripheral resistance were calculated.

Pregnancies were categorized on the basis of the first hemodynamic measurement made after the end of the first trimester. High-resistance hypertension was defined by a total peripheral resistance ≥ 1150 dynes · cm · sec⁻⁵. Low resistance hypertension was defined by a total peripheral resistance <1150 dynes · cm · sec⁻⁵.

The hemodynamics of patients on antihypertensive therapy were examined to determine if therapy would be likely to result in an inappropriate categorization. For example, a patient with high cardiac output, low-resistance hypertension treated with a β -adrenergic receptor blocker could be accurately placed in the low-resistance group; lowered resistance would not be expected to be the result of β -adrenergic receptor blockade. On the other hand, a patient with low-resistance hypertension treated with a vasodilator such as hy-

dralazine could not be accurately characterized. These patients were excluded from the study.

All patients had follow-up with hemodynamic measurements until the end of pregnancy. In a small number of cases we observed that in subsequent measurements the hemodynamic pattern crossed over from low-resistance to high-resistance hypertension. These pregnancies were placed in a third group, crossover.

Birth weights were abstracted from the mothers' medical charts. Gestational age was determined by best obstetric parameter. Percentile birth weight was calculated from normative data for births at sea level.4 Intrauterine growth retardation was defined as birth weight at <10th percentile for gestational age.

Statistical analysis was performed by analysis of variance, χ^2 , and Fisher's exact tests.

Results

Seventy-six pregnancies that met study criteria were identified: 36 low-resistance, 32 high-resistance, and eight crossover. Only one could not be adequately characterized because of hypertensive therapy. Maternal characteristics are listed in Table I. Women with lowresistance hypertension were 19 kg heavier than those with high-resistance hypertension (p < 0.001). Women who crossed over were intermediate in weight between the two groups. The rates of nulliparity, chronic hypertension, and proteinuria were similar among the groups.

Initial individual maternal hemodynamics are displayed graphically in Fig. 1, where mean arterial pressure is plotted against cardiac output. Summary statistics are listed in Table II. The groups were partitioned

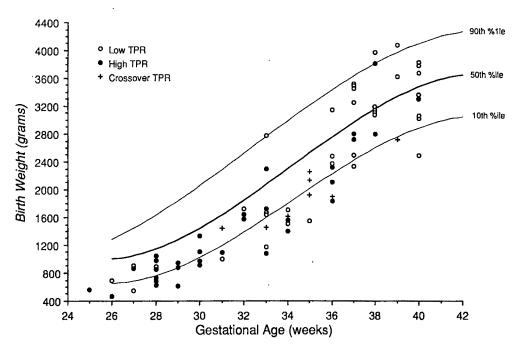

Fig. 2. Fetal growth. Individual birth weights are plotted against gestational age. The 10th, 50th, and 90th percentiles of normal birth weights at sea level are included for reference. *Closed circles*, Infants from high-resistance pregnancies; open circles*, infants from low-resistance pregnancies; plus signs, infants from crossover pregnancies.

Table II. Maternal hemodynamics

	Low-resistance	p ₁	High-resistance	<i>p</i> ₂	Crossover	p ₃
Heart rate (beats/min)	93 ± 14	0.001	79 ± 14	0.05	91 ± 14	NS
Mean arterial pressure (mm Hg)	106 ± 8.4	0.001	113 ± 8.6	NS	115 ± 15	0.01
Cardiac output (L/min)	9.6 ± 1.3	0.001	$6.4 \pm .91$	0.01	9.8 ± 1.5	NS
Stroke volume (ml/min)	105 ± 17	0.001	84 ± 16	0.01	105 ± 15	NS
Total peripheral resistance (dyne · cm · sec ⁻⁵)	862 ± 166	0.001	1427 ± 199	0.001	974 ± 111	NS

Values are mean \pm SD. p_t , Low-resistance versus high-resistance; p_2 , high-resistance versus crossover; p_3 , crossover versus low-resistance; NS, p > 0.05.

by vascular resistance, so the differences in resistance, cardiac output, and stroke volume were expected. The mean arterial pressures of both the high-resistance and crossover groups were higher than that of the low-resistance group (p < 0.001, p < 0.01). Mean heart rates of the low-resistance and crossover groups were higher than that of the high-resistance group (p < 0.001, p < 0.05).

Birth weight is plotted against gestational age for each study infant in Fig. 2. Summary statistics are listed in Table III. Infants of mothers with high-resistance hypertension were delivered 4 weeks earlier than those of women with low-resistance hypertension (p < 0.001). Given the large difference in gestational age, a large difference in birth weight was expected (p < 0.001). The mean percentile birth weight of infants born to women with high-resistance hypertension was 19th compared with 39th for infants born to women in the low-resistance group (p < 0.005). Differences in

the rates of intrauterine growth retardation corresponded to differences in percentile birth weights.

The mean gestational age of infants in the crossover group was similar to that in the low-resistance group. However, the infants in the crossover group exhibited growth retardation similar to that seen in the high-resistance group. In addition, they experienced a very high rate of fetal death (38%). In one case antepartum testing was very abnormal, but the patient repeatedly refused admission to the hospital. In the other two the patients had reactive nonstress tests without decelerations <3 days from the fetal death.

Comment

The hemodynamics of hypertension in pregnancy have been the subject of considerable controversy. Previous notions that vasoconstriction uniformly mediates all hypertensive disease in pregnancy have been challenged by numerous cross-sectional studies of patients

Table III. Neonatal outcome

	Low-resistance	p_1	High-resistance	p ₂	Crossover	p ₃

near delivery5-11 and by our recent longitudinal study of uncomplicated nulliparous patients who developed preeclampsia.12 In this study we have documented the marked heterogeneity of hemodynamics exhibited by women who become hypertensive early in pregnancy (Fig. 2). We have also documented the potential for women with high-output, low-resistance hypertension to cross over to high-resistance hypertension in the course of pregnancy. We have previously suggested that this Guytonean model of hypertension,18 where an individual may progress from high-output to high-resistance hypertension, may explain the complexity and heterogeneity of hypertension in pregnancy. 12, 14

We examined the relationship between fetal outcome and the hemodynamic characteristics of the mothers' hypertension. Infants born to women with high-resistance hypertension required delivery for fetal or maternal indications 4 weeks earlier in pregnancy. In addition, these infants were much smaller for gestational age. Increased prematurity, coupled with an increased rate of growth retardation, resulted in infants with dramatically smaller birth weights. These findings are consistent with those of Nisell et al.15 We hypothesize that global vasoconstriction in women with high-resistance hypertension is associated with decreased uteroplacental blood flow and poor fetal growth.

In Fig. 2 one can see that impaired fetal growth is nearly uniform in the high-resistance group. Only two infants were above the 50th percentile. However, such uniformity is not present in the low-resistance group. Although many infants were normally grown and a few were macrosomic, eight (22%) were at <10th percentile. Despite a global condition characterized by increased perfusion, the uteroplacental bed in these pregnancies seems to be underperfused; aberrations in the regional circulation of some women in the low-resistance group may not be adequately characterized by assessment of total peripheral resistance. We hypothesize that the vessels of the uteroplacental bed are more susceptible to hemodynamic injury than the remainder of the circulation and therefore may cross over to a high-resistance state earlier than the systemic circulation as a whole.

The group of patients whose systemic hemodynamics

crossed over are particularly interesting. However, the small size of the group has limited statistical power, and the results should therefore be interpreted cautiously. Initially, the patients in the crossover group were similar to patients in the low-resistance group. Their mean cardiac output and mean heart rate were the same. They did have a higher mean arterial pressure, suggesting more severe hypertension.

Infants from this group were different from each of the other groups. First, they were undergrown, comparable to the high-resistance group. The degree of growth retardation suggests that alterations in uteroplacental blood flow had been present for a considerable period of time while the systemic circulation was hyperdynamic. Second, shortly after systemic hemodynamic crossover we observed a high rate of intrauterine fetal death. In two cases the observable change in fetal environment was very abrupt and corresponded to systemic vasoconstriction. In these patients, before vasoconstriction, the underlying degree of uteroplacental insufficiency was adequately compensated. In this context an abrupt reduction in blood flow associated with systemic vasoconstriction had lethal consequences. We were impressed with the rapidity of deterioration of the fetal environment. At present in our practice the crossover of maternal hemodynamics in hypertensive patients is considered a critical event that requires intense fetal surveillance.

Many of the patients in the study, if managed expectantly, were treated with antihypertensive agents. Could antihypertensive therapy be responsible for some of the findings in this study? We believe that this is unlikely. In general, patients in the high-resistance group were treated with vasodilators, primarily hydralazine. Patients in the low-resistance group were treated with a β-adrenergic receptor blocker, primarily atenolol. If the patients' hemodynamics changed during the course of therapy, the antihypertensive regimen was altered accordingly. We have previously demonstrated that hydralazine and atenolol, when used in high- and low-resistance groups, respectively, have predictable effects on maternal hemodynamics.16 Hydralazine lowers resistance and atenolol tends to increase resistance; therefore the effects of these drugs would work to reduce differences between groups rather than to increase them.

We have demonstrated clear correlations between fetal outcome and maternal hemodynamics in hypertensive patients. A vasoconstricted maternal circulation is associated with early delivery and impaired fetal growth. In addition, we present evidence to suggest that the uteroplacental circulation may adjust independently from the maternal circulation; being more sensitive to forces that lead to vasoconstriction, regional crossover may occur earlier in pregnancy. Crossing over to high-resistance hypertension in the third trimester is a particularly morbid event. Outcomes are worse than those seen with chronic vasoconstriction. We find this event to be an important clinical marker for the need for increased fetal surveillance.

Magnesium sulfate versus phenytoin for seizure prophylaxis in pregnancy-induced hypertension

Margaret P. Appleton, MD, Thomas J. Kuehl, PhD, Marsha A. Raebel, PharmD, H. Ray Adams, PhD, Alfred B. Knight, MD, and William R. Gold, MD Temple, Texas

Seizure prophylaxis is standard intrapartum therapy for patients with pregnancy-induced hypertension. Magnesium sulfate is used in the United States in spite of limited literature comparing its efficacy with other anticonvulsants. Fifty patients with pregnancy-induced hypertension were prospectively randomized to receive magnesium sulfate or phenytoin for seizure prophylaxis. Patients were observed for toxicity, side effects, and labor outcomes, and the neonates were evaluated for side effects of the therapy. Three patients were excluded with adverse reactions to medications (one in magnesium sulfate group, two in phenytoin group). No differences were found in patient tolerance, adverse reactions, or neonatal outcomes between groups. Maternal free phenytoin levels were 13.0% ± 0.4% of total phenytoin (serum albumin, 2.5 to 3.5 gm/dl), significantly higher than in nonpregnant patients. Neither free phenytoin levels nor percentage of total phenytoin that was free correlated significantly with maternal albumin levels. The pharmacokinetics of phenytoin loading in the massively obese pregnant patient may differ and require further evaluation. Phenytoin is a well-tolerated alternative to magnesium sulfate for seizure prophylaxis in the patient with mild pregnancy-induced hypertension. (AM J OBSTET GYNECOL 1991;165:907-13.)

Key words: Pregnancy-induced hypertension, seizure prophylaxis, magnesium sulfate, phenytoin

Magnesium sulfate is the standard of care in the United States for seizure prophylaxis in pregnancyinduced hypertension,1 although its efficacy has not been substantiated when compared with other anticonvulsant agents such as phenytoin.24 Recent studies have addressed phenytoin pharmacokinetics and efficacy in patients with pregnancy-induced hypertension. 5-9 The following hypotheses were proposed to evaluate other aspects of therapy in 50 patients prospectively randomized to magnesium sulfate or phenytoin.

- 1. The safety of phenytoin, as defined by intrapartum complications and adverse reactions, will compare favorably with magnesium sulfate in the term and near-term pregnant patient with pregnancy-induced hypertension.
- 2. There will be better patient tolerance of side effects with phenytoin compared with magnesium sulfate as demonstrated by patient and nursing questionnaires.
- 3. Neonatal outcome will not differ in the two groups.

Therapeutic phenytoin levels are a function of the percentage of phenytoin not bound (free phenytoin).6 Generally, 90% of plasma phenytoin is present as an inactive form bound to albumin. The phenytoin level measured clinically is total (bound and free) phenytoin. Because albumin levels are decreased in pregnancy and in pregnancy-induced hypertension, total phenytoin levels may not reflect the ratio of free to total phenytoin, and therefore a different therapeutic range for total phenytoin has been proposed.6 Serum free and total

phenytoin, albumin, and total protein concentrations

were measured to further evaluate this concept.

Material and methods

Subjects. From November 1989 to November 1990, 50 patients with pregnancy-induced hypertension, at ≥36 weeks' gestation, were prospectively randomized to prophylaxis with magnesium sulfate or phenytoin. Eleven patients met criteria for severe pregnancy-induced hypertension, and one had an eclamptic seizure before admission. The remaining had mild pregnancyinduced hypertension. Laboratory monitoring included urinalysis, complete blood cell count, platelet count, liver enzymes, and clotting parameters.

Protocol for magnesium sulfate. The 4 gm loading dose (100 ml of a solution containing 40 gm magnesium sulfate diluted in 1000 ml 5% dextrose in water) was infused intravenously over 20 minutes. The maintenance dosage was initiated by continuous infusion at 2 gm/hr (50 ml/hr of same solution) and was adjusted

†Results expressed as mean ± SD.

to serum levels between 4 and 7 mg/dl. Serum Mg²⁺ levels were measured every 6 hours.

Protocol for phenytoin. An initial loading dose of 10 mg/kg was infused intravenously at a rate of 25 to 40 mg/min, followed 2 hours later by an additional dose of 5 mg/kg as per Ryan et al.⁶ Blood pressure and pulse were recorded every 2 minutes during infusion and every 15 minutes thereafter. Continuous electrocardiac monitoring was used during infusion only. A maintenance dose of 200 mg was initiated 12 hours after the second loading dose and repeated every 8 hours. This dose was given intravenously during the intrapartum period and orally post partum for 24 hours and was then discontinued. Free and total serum phenytoin levels, albumin, and total protein were measured 8 and 14 hours after the initial loading dose.

Common aspects of both protocols. All patients were cared for in our intensive observation unit for 24 hours post partum, were given nothing by mouth, had vital signs taken every 15 minutes, had hourly intake and output checks, and had indwelling bladder catheters. Twenty-four hours post partum the seizure prophylaxis was discontinued, and the patients were transferred to the postpartum unit.

Patients and nurses were asked to complete a questionnaire between 24 and 36 hours post partum. Each was asked to rank (between 1 and 5) the following char-

acteristics by severity, with low numbers representing little or no problem and high numbers severe or constant problem: nausea or vomiting, blurred or double vision, drowsiness, and difficulty speaking. Apgar scores, umbilical cord arterial and venous blood gas values, and neurologic evaluation were obtained on all neonates. Magnesium sulfate, total and free phenytoin, and total protein and albumin concentrations were determined in umbilical cord serum for the appropriate groups.

Phenytoin and plasma protein assays. Serum protein and albumin were assayed by standard methods, and total phenytoin was assayed on an Abbott TDX (Abbott Laboratories, Chicago) by fluorescence polarization immunoassay. Free phenytoin levels were determined in batches of samples after ultrafiltration to remove plasma proteins using the technique described by Oellerich and Muller-Vahl. 10, 11

Informed consent. The study was approved by the Institutional Review Board of Scott and White Memorial Hospital. Informed consent was obtained from each patient before enrollment in the protocol.

Statistical methods. Groups were compared with statistical techniques, including analysis of variance and the Student t test, for characteristics expressed as continuous variables, χ^2 analysis to test characteristics expressed as proportions, and the Mann-Whitney U test to test characteristics expressed as noncontinuous or nonparametric variables. Comparisons were also made with multifactorial or single-factor analysis of variance when appropriate. Software used included PC Statistician and PC ANOVA (Human Systems Dynamics, Northridge, Calif.).

Results

Fifty patients were randomized by ordered packets to two groups, magnesium sulfate or phenytoin. Three patients were excluded. The remaining patients (24 in magnesium sulfate group and 23 in phenytoin group) completed the protocol. No differences were evident between the antepartum clinical characteristics of the two groups (Table I). Intrapartum characteristics (Table II) demonstrate no significant differences in incidence of cesarean section, dose-to-delivery intervals, and duration of second stage of labor. A difference of 2.5 hours between the lengths of first stage of labor was observed, but this did not reach statistical significance. The length of hospitalization for vaginally delivered phenytoin patients was also shorter than that for the magnesium sulfate patients, but this difference was not statistically significant (p = 0.06).

Both protocols were safe and well tolerated. No seizures occurred in either group. Three patients were excluded for adverse reactions; one patient became extremely anxious 30 seconds after starting the magne-

3.3

sium sulfate loading dose and demanded discontinuance of the drug. Two patients were excluded from the phenytoin group, one for itching (without rash) that occurred after the second loading dose and the other for symptomatic hypotension (blood pressure from 200/100 to 120/60 mm Hg) and dysphoria that occurred during initial phenytoin infusion. The latter patient had a phenytoin level of 13.4 µg/ml, well within the therapeutic range. This reaction may have been ameliorated by slowing the infusion rate further to <25 mg/min. Each of these patients received the other drug during labor without sequelae and were excluded from further evaluation. Burning at the intravenous injection site was noted by one other patient receiving phenytoin.

Patients and their nurses reported mild side effects (Table III) with no differences between mean or total scores for the four characteristics. The nursing and patient scores correlated well.

No neonatal adverse outcomes were documented. Apgar scores (1 min, 7.4 vs 7.8; 5 min, 8.9 vs 9.0), umbilical cord blood gases (artery, 7.26 ± 0.06 vs 7.25 ± 0.03), and birth weights (3110 ± 615 vs 3122 ± 602 gm) were not different between groups and were normal. The initial and discharge physical examinations, including the neurologic examination, were within normal limits. All babies went home with their mothers (one baby with intrauterine growth retardation was observed two days), and length of hospitalization was not different in the two groups (3.1 ± 0.4) days for magnesium sulfate infants and 2.5 ± 0.3 days for phenytoin infants). There was a preponderance of male neonates in our study (32 male, 15 female).

Magnesium sulfate levels were therapeutic at initial evaluation in 22 of 24 patients. Neonatal levels paralleled maternal levels (Fig. 1).

Twenty-two of 23 patients receiving phenytoin had free levels between 1 and 2 µg/ml, considered to be the therapeutic range. Neonatal free and total phenytoin levels are shown by intervals from first dose (Fig. 2). With the nonpregnant total phenytoin therapeutic range (10 to 20 μg/ml), nine of 27 maternal samples would have been considered subtherapeutic. Serum albumin concentrations were very similar within the three groups of samples (two maternal and one neonatal group) but differed from each other and correlated to percent free phenytoin (Fig. 3). The correlation coefficient was low ($R^2 = 0.36$; percent free phenytoin = 19.9 - 2.29 [albumin]), suggesting that low serum albumin explains only a small proportion (36%) of the increase in free phenytoin. In the two maternal samples free phenytoin (mean ± SE) was 13.1% ± 0.4% (range, 9.5% to 16.0%) and $13.9\% \pm 0.5\%$ (range, 9.2% to 14.3%), significantly greater than in neonatal samples, $10.2\% \pm 0.7\%$ (range, 9.2% to 14.2%).

2.6

One patient had levels above the normal therapeutic range for both total and free (21.1 and 2.8 µg/ml, respectively); neonatal levels reflected these high maternal levels (total, 23.8 µg/ml; free, 2.6 µg/ml). The total loading dose, 2400 mg, was calculated from the patient's weight (>350 pounds). Neither the patient nor her neonate had clinical symptoms of phenytoin tox-

Comment

Most patients with pregnancy-induced hypertension do not progress to seizures. However, identification of the subgroup of patients who are at greatest risks for seizures (for example, by providing prophylaxis for only those patients with severe pregnancy-induced hypertension or hyperreflexia) may increase specificity but not sensitivity. Hence, at our institution all patients who meet clinical criteria for pregnancy-induced hypertension receive intrapartum seizure prophylaxis.

Both magnesium sulfate and phenytoin are associated with risks and side effects. 6, 12 Magnesium sulfate can produce nausea, blurred vision, drowsiness, and depression of the deep tendon reflexes at therapeutic

^{*}Comparisons made with multifactorial or single-factor analysis of variance. There were no significant interactions between type of treatment and mode of delivery.

[†]Comparisons of nulliparous patients delivered vaginally made with single-factor analysis of variance. No significant differences. ‡Only significant difference in this series of comparisons was for the effect of mode of delivery on length of hospital stay (p = 0.011).

levels (4 to 7 mg/dl). At plasma levels above 10 mg/dl respiratory depression can occur. The patient who was reported to have an adverse reaction on magnesium sulfate likely had an emotional reaction to medication rather than a true toxic response.

The side effects of phenytoin during short-term use are also dose-dependent and have been mild in other studies. When serum total phenytoin levels exceed 20 $\mu g/ml$, a significant risk of nystagmus occurs. At 30 $\mu g/ml$ ataxia and incoordination are observed. Because we have had limited experience with intravenous phenytoin, we chose to be particularly cautious. The first patient excluded from the phenytoin group had diffuse itching without a rash. This reaction may have been

^{*}No sigificant differences between groups for either patient or nurse responses to questions about side effects. Mann-Whitney U test used for group comparisons.

related to the coincidental placement of a bupivacaine hydrochloride and fentanyl epidural block. The second patient excluded from the phenytoin group had a known phenytoin reaction (hypotension) that can be appropriately treated by slowing the rate of infusion. No patient's outcome was altered by these reactions.

We had anticipated that the side effects of phenytoin would be significantly fewer than those of magnesium sulfate. Both regimens were tolerated well, as documented by our patients and their nurses. For the purpose of this study, patients receiving phenytoin were not managed differently from patients receiving magnesium sulfate. Much of the intensive monitoring of mild pregnancy-induced hypertension in postpartum patients is required because of the potential side effects

of magnesium sulfate. This monitoring protocol could be simplified if the patient were on phenytoin. Indeed, even the continuous electrocardiographic monitoring may not be necessary during phenytoin loading doses in mild pregnancy-induced hypertension in patients without cardiac disease. Our study suggests a shorter length of hospitalization in phenytoin-treated patients delivered vaginally. Our impression is that phenytointreated patients felt better more quickly and were likely to be discharged earlier. However, length of hospitalization was not a part of the study hypotheses, and therefore variables relating to length of stay were not controlled.

No adverse effects were noted in the neonates. Toxic effects of magnesium sulfate on the neonate have been suggested, postulated, and in general, not supported. Phenytoin is used in neonates to treat seizures with few complications.¹⁸

No patient in either group had seizures after the initiation of prophylaxis. However, the small number of patients in our study does not allow an assessment of efficacy for seizure prevention. Dommisse8 has challenged phenytoin's ability to prevent recurrence of seizures in eclamptic patients. Four of 11 of his patients treated with phenytoin had recurrent seizures in spite of therapeutic levels of total phenytoin, whereas none of the 11 patients on magnesium sulfate had recurrent seizures. Free phenytoin levels were not measured. Ten percent to fifteen percent of eclamptic patients will have recurrent seizures in spite of therapeutic anticonvulsant levels,12 and many eclamptic patients have central nervous system pathology that would predispose them to repetitive seizures.14 Persistent seizures after treatment with phenytoin has recently been reported by Coyaji and Otiv.9 Ryan15 has proposed a multicentered study to address the efficacy of seizure prophylaxis in a response to Dommisse's report. Indeed, phenytoin may offer less advantage to the patient with severe pregnancy-induced hypertension or the eclamptic patient. Intensive monitoring of these patients for at least 24 hours post partum would be necessary, independent of the anticonvulsant used.

For most drugs the rate of metabolism is directly proportional to the plasma concentration, i.e., the pharmacokinetics are first-order. This is not true for phenytoin, a drug that has capacity-limited or saturable metabolism. For most patients the rate of phenytoin metabolism at therapeutic plasma concentrations is close to the limit. Small dosage adjustments within the therapeutic range can lead to disproportionate increases in both plasma total and free phenytoin concentrations. Saturation of the enzyme systems responsible for phenytoin metabolism is often the cause of phenytoin toxicity; careful attention to phenytoin dosing is therefore appropriate.

There was not a wide variance in albumin or total protein levels among our patients. A concern that the maternal low protein levels (specifically albumin) would increase the percentage of free phenytoin and thus increase toxicity was not substantiated. Ryan et al.⁶ proposed a different therapeutic range for total phenytoin during pregnancy, 7 to 17 µg/ml (nonpregnant, 10 to 20 µg/ml), on the basis of the decrease in albumin levels. Their therapeutic ranges are derived from a formula that adjusts the total phenytoin for the patients' albumin levels. Neither their formula nor others in their reference¹⁶ accurately estimate free phenytoin levels in our patient population. Beck et al.¹⁷ attempted to estimate free phenytoin levels with multiple serum biochemical and clinical parameters. Serum albumin

level was the primary variable, but it alone explained at best 77% of the observed free phenytoin variability $(C_F = 1.53 + [0.09 \ C_T] - 0.43$ albumin, where C_F is free phenytoin and C_T is total phenytoin clearance). Factors known to affect binding of phenytoin to albumin include liver disease, renal disease (elevated blood urea nitrogen), elevated liver enzymes (specifically aspartate aminotransferase), and elevated bilirubin. An increased free fatty acids level may alter the percentage of free phenytoin. Free fatty acid levels were not measured in our patients.

This study confirms the work of Ryan et al.,6 in which a two-phase loading dose of phenytoin was proposed (range of our loading doses was 675 to 1930 mg, excluding the patient mentioned below). Free phenytoin levels were therapeutic and relatively independent of total phenytoin levels. The single exception was a morbidly obese young woman whose loading dose was 2400 mg; she had no clinical symptoms suggestive of a toxic dose. It is possible that the high plasma levels observed in our morbidly obese patient reflect a patient with a low metabolic capacity for phenytoin and not solely an obesity effect. A maximum loading dose of 2100 mg is suggested until larger studies can address the additional problem of the pregnant obese patient.

In our study no alteration in dosing was made on the basis of total phenytoin concentration. Whether monitoring of free phenytoin levels or total levels by using an adjusted therapeutic range is appropriate cannot be decided by this study. Phenytoin is commonly used to treat seizure disorders during pregnancy. The dose of phenytoin is often increased on the basis of the lower serum total levels found during pregnancy. Our study suggests that the free component of phenytoin is likely still in the therapeutic range and that increasing the dose is unnecessary.

In summary, this study confirms that both magnesium sulfate and phenytoin, when used for seizure prophylaxis, have limited side effects and are well tolerated by patients and neonates. Patients with mild pregnancyinduced hypertension (at least 70% of our patients) who are at low risk for seizures could benefit from the reduced intensity of monitoring acceptable with intravenous phenytoin therapy. The comparative efficacy of seizure prophylaxis with phenytoin or magnesium sulfate or simply expectant management of patients with pregnancy-induced hypertension must await a randomized, multicentered clinical trial. To determine the size of a proposed trial, we estimate the incidence of eclampsia to be approximately 1% of patients with pregnancy-induced hypertension; half have seizures before receiving medical care. To detect a 50% change in seizure incidence ($\alpha = 0.05$, power = 0.8), a patient population of about 9100 would be required. The patient who has seizures before admission or who has

severe pregnancy-induced hypertension may constitute a unique subgroup of patients and should be evaluated separately in any proposed trial.

We thank our nursing and resident staff for their assistance in this project.

Editors' note

The American Journal of Obstetrics and Gynecology introduces a new format for abstracts accompanying regular articles, society articles, and Current Investigation articles. Authors submitting these manuscripts to the JOURNAL should provide an abstract of no more than 150 words structured according to the following headings: Objective(s), Study Design, Results, and Conclusion(s). Exceptions to this requirement include Clinical Opinion, Current Development, case reports, and brief communications articles. Abstracts for these articles will continue to follow the standard abstract format. Please consult the Information for Authors for details.

Incidence and risk factors associated with abnormal postpartum glucose tolerance in women with gestational diabetes

Patrick M. Catalano, MD,^a Kathleen M. Vargo, MD,^a Ira M. Bernstein, MD,^b and Saeid B. Amini, PhD^a

Cleveland, Ohio, and Burlington, Vermont

To determine the incidence and risk factors associated with an abnormal postpartum glucose tolerance in women with gestational diabetes, 103 patients with gestational diabetes had a 2-hour, 75 gm oral glucose tolerance test 6 ± 2 weeks (mean \pm SD) after delivery. Twenty-two percent (23/103) of results were abnormal: Three showed frank diabetes, four showed impaired glucose tolerance, and 16 were nondiagnostic. There was a significant difference in gravidity, pregravid weight and body mass index, delivery weight, gestational age at diagnosis, fasting and 2- and 3-hour glucose level at the time of the oral glucose tolerance test during pregnancy, need for insulin therapy during gestation, and neonatal weight >4000 gm in the abnormal group as compared with the normal group. Elevated fasting glucose level (p = 0.0001) and earlier gestational age at time of diagnosis of gestational diabetes (p = 0.013) were found to be most predictive of an abnormal postpartum glucose tolerance test result. These results support the importance of postpartum oral glucose tolerance testing in women with gestational diabetes. (AM J OBSTET GYNECOL 1991;165:914-9.)

Key words: Postpartum glucose tolerance, gestational diabetes

Gestational diabetes is the most common metabolic abnormality affecting pregnant women. Approximately 3% of all pregnant women have gestational diabetes, representing 80% of all pregnancies complicated by diabetes mellitus. Women with gestational diabetes have an increased risk for developing diabetes mellitus in later life. The prevalence of diabetes in the 15-year follow-up studies of O'Sullivan³ ranged between 25% and 50% in lean and obese women with gestational diabetes, whereas it was only 2% and 4% in lean and obese women with normal glucose tolerance during gestation. Others have also found an increased risk of overt diabetes mellitus in different populations in later life. 4.5

On the basis of these findings, the Second International Workshop-Conference on Gestational Diabetes⁶ has recommended that all women in whom a diagnosis of gestational diabetes was made should be evaluated

at the first postpartum visit by a 2-hour, 75 gm oral glucose tolerance test (GTT) in accordance with the criteria of the National Diabetes Data Group or World Health Organization. The only study to date that has examined the outcome of this recommendation was the recent study by Kjos et al. They found a 19% (48/246) incidence of abnormal oral glucose tolerance in the early postpartum period in a primarily Hispanic population (98%) of women with gestational diabetes. Hence, the purpose of our study was to determine the incidence of abnormal postpartum glucose tolerance in women with gestational diabetes in our population and to evaluate which risk factors are predictive of an abnormal result.

Methods

Subjects. This retrospective study was carried out at MetroHealth Medical Center, Cleveland, and the Medical Center Hospital of Vermont, Burlington. Maternal and neonatal records from patients with gestational diabetes from 1987 through 1989 were reviewed. Most of the patients received their primary obstetric care at these hospitals, although some patients were referred from outlying physicians to the Maternal-Fetal Medicine service. All obstetric patients were screened for gestational diabetes using a 50 gm, 1-hour oral glucose load between 24 and 28 weeks' gestation. Women with risk factors for gestational diabetes (previous gestational diabetes, history of fetal macrosomia, prior still-birth, persistent glucosuria, maternal obesity, and fam-

ily history of type II diabetes mellitus) were screened at their initial visit and again at 24 to 28 weeks' gestation. Patients with a venous plasma glucose value of >135 mg/dl underwent a 100 gm, 3-hour oral GTT. All patients were instructed to follow a diet that provided at least 150 gm carbohydrate for 3 days and to fast for at least 10 hours before the GTT. The diagnosis of gestational diabetes was made with the criteria of Carpenter and Coustan,8 i.e., two or more of these venous plasma glucose concentrations were met or exceeded: fasting, 95 mg/dl; 1 hour, 180 mg/dl; 2 hours, 155 mg/dl; and 3 hours, 140 mg/dl.

All patients with gestational diabetes were instructed in diet therapy by a registered dietician. The diet consisted of 30 to 35 kcal/kg ideal body weight, 50% of the calories as complex carbohydrates and the remaining calories as fat, 80 to 100 gm protein, and 20 gm dietary fiber. Women with gestational diabetes either performed home blood glucose monitoring or had weekly fasting and postprandial glucose determinations in the pregnancy diabetic clinic. Insulin therapy was instituted if fasting or preprandial glucose determinations were consistently >100 mg/dl or 2-hour postprandial glucose determinations were >120 mg/dl. None of the patients were started on prophylactic insulin therapy. The characterization of neonatal birth weight as small for gestational age (SGA, <10th percentile), average for gestational age (AGA, between 10th and 90th percentiles), and large for gestational age (LGA, >90th percentile) was based on normative birth weight curves for gestational age developed at each hospital by one of the authors (P.M.C.). Maternal estimates of obesity were described with the body mass index: Weight (kilograms)/Height (meters)2.

All patients with gestational diabetes were urged to have a 2-hour, 75 gm oral GTT at the time of the postpartum visit. They were again instructed to consume ≥150 gm carbohydrate per day for 3 days and fast for at least 10 hours before the GTT. Plasma glucose values were obtained in the fasting state and then at 30, 60, 90, and 120 minutes after the glucose ingestion. Glucose concentrations were measured with the glucose oxidase method in the hospital or Clinical Research Center laboratory. Postpartum oral GTTs were interpreted according to the criteria of the National Diabetes Data group.9 The diagnosis of diabetes mellitus in nonpregnant adults is made either by an elevated venous plasma glucose level >140 mg/dl or by the 2-hour venous plasma glucose sample and any one of the 30-, 60-, or 90-minute venous plasma glucose samples >200 mg/dl. Three criteria are needed for the diagnosis of impaired glucose tolerance: (1) fasting venous plasma glucose level <140 mg/dl, (2) venous plasma glucose concentration at 30, 60, or 90 minutes >200 mg/dl, and (3) 2-hour venous plasma glucose concentration between 140 and 200 mg/dl. Normal glucose tolerance is defined as (1) fasting venous plasma glucose level <115 mg/dl, (2) 30-, 60-, and 90-minute venous plasma glucose concentrations <200 mg/dl, and (3) 2-hour venous plasma glucose concentration <140 mg/dl. Venous plasma glucose concentrations above those defined for normal glucose tolerance but below the criteria for impaired glucose tolerance are considered nondiagnostic.

Statistical analysis. The data are expressed as mean ± SD. The difference between groups was determined by unpaired Student t test, two-sample Wilcoxon test, χ^2 analysis, or generalized Fisher's exact test. Stepwise logistic regression analysis was used to determine which risk factors were most predictive of an abnormal postpartum GTT. Statistical analyses were performed with a BMDP statistical software package. Probability levels of ≤0.05 were considered significant.

Results

We were able to review 115 maternal and neonatal records of women who had gestational diabetes and a 2-hour, 75-gm GTT at their postpartum visit. Twelve patients were excluded from analysis because of incomplete records. Thus 103 patient records were included in the final analysis. Of these, 46 were from the Case Western Reserve University and 57 were from the University of Vermont.

Our study population consisted of 82% white, 6% black, 6% Hispanic, and 6% other (Asian, Middle Eastern, mixed) patients. Forty-nine percent of these women had a positive family history of diabetes mellitus, and 20% had a previous history of gestational diabetes. Fifty-one women (49%) required insulin therapy for glucose control at some time during their pregnancy.

The postpartum GTTs were completed at 6.6 ± 1.6 weeks after delivery. Forty-four (43%) of women were breast-feeding, and nine (9%) were using oral contraceptives at the time of the postpartum GTT. Twentythree (22%) of the 75 gm, 2-hour GTTs were abnormal: three, frank diabetes mellitus; four, impaired glucose tolerance, and 16, nondiagnostic.

We next compared the maternal and neonatal characteristics of the patients with normal and abnormal postpartum glucose tolerance (Table I). There was a significant difference in gravidity $(3.7 \pm 2.4 \text{ vs})$ 2.8 ± 1.9 ; p = 0.05), pregravid weight (84.6 ± 18.3 vs $71.8 \pm 20.0 \,\mathrm{kg}$; p = 0.002), pregravid body mass index $(32.5 \pm 6.8 \text{ vs } 27.2 \pm 7.6 \text{ kg/m}^2; p = 0.003)$, and delivery weight $(97.6 \pm 16.3 \text{ vs } 84.3 \pm 17.0 \text{ kg})$ p = 0.001) in women with abnormal postpartum glucose tolerance as compared with the normal group. Gestational age at the time of diagnosis of gestational diabetes (22.4 \pm 7.7 vs 27.7 \pm 6.1 weeks' gestation; p = 0.0009) was significantly less in the abnormal post-

partum glucose tolerance group as compared with the normal group. Although approximately 30% of the neonates in each group were LGA, there were significantly more infants (7/23, 30%, vs 9/80, 11%; p = 0.03) of mothers with gestational diabetes who were >4000 gm in the abnormal postpartum glucose tolerance group as compared with the normal group. There were more male than female neonates of these woman (60 male vs 43 female; p = 0.09); however, this did not reach statistical significance.

The maternal data relating to glucose tolerance are

given in Table II. The fasting (117.4 \pm 26.1 vs 96.5 \pm 13.2 mg/dl; p=0.0001), 2-hour (206.2 \pm 51.1 vs 185.0 \pm 30.1 mg/dl; p=0.015), and 3-hour (154.7 \pm 56.1 vs 128.2 + 33.2 mg/dl; p=0.007) glucose concentrations during gestation were significantly greater in the abnormal postpartum GTT group than in the normal group. Furthermore, 18 (78%) of the patients with abnormal postpartum glucose tolerance required insulin therapy during gestation as compared with 32 (40%) of the patients with normal postpartum glucose tolerance (p=0.003).

With the use of stepwise logistic regression analysis adjusted for any possible location difference, fasting glucose level at the time of the oral GTT (p = 0.0001) during gestation and gestational age at the time of the abnormal test (p = 0.013) were the best predictors of abnormal postpartum glucose tolerance in these women. Although not significant, the next best predictor of abnormal postpartum glucose tolerance was insulin therapy during gestation (p = 0.08).

Because 16 of the patients in the abnormal group had a nondiagnostic postpartum GTT result, we further analyzed the data comparing the seven women with frank glucose intolerance (three with diabetes mellitus, four with impaired glucose tolerance) with the 80 women with normal postpartum glucose tolerance. The results are given in Tables III and IV. Maternal age $(33.7 \pm 3.0 \text{ vs } 29.3 \pm 5.6 \text{ years; } p = 0.03)$, gravidity $(4.7 \pm 2.9 \text{ vs } 2.8 \pm 1.9; p = 0.04)$, and pregravid weight (86.0 \pm 20.1 vs 71.8 \pm 20.0 kg; p = 0.05) were significantly greater in the women with frank glucose intolerance than in the women with normal postpartum glucose tolerance. Estimated gestational age at the time of diagnosis of gestational diabetes was again earlier and highly significant in the women with frank glucose intolerance (19.0 \pm 9.2 vs 27.7 \pm 6.1 weeks' gestation; p = 0.006) as compared with the other group. Although estimated gestational age at the time of delivery was earlier in the women with frank glucose intolerance $(36.4 \pm 3.8 \text{ vs } 38.4 \pm 1.5 \text{ weeks' gestation; } p = 0.17),$ the incidence of neonatal weight >4000 gm was significantly greater (3/7, 43%, vs 9/80, 11%; p = 0.05) in these seven patients as compared with the women with normal postpartum glucose tolerance.

The maternal data relating to glucose tolerance in these 87 patients are given in Table IV. The fasting $(136.6 \pm 24.8 \text{ vs } 96.5 \pm 13.2 \text{ mg/dl}; p = 0.0001),$ 1-hour $(250.4 \pm 36.6 \text{ vs } 206.5 \pm 23.6 \text{ mg/dl}; p =$ 0.001), 2-hour (224.3 \pm 73.2 vs 185.0 \pm 30.1 mg/dl; p = 0.03), and 3-hour (200.3 ± 68.2 vs 128.2 ± 33.2 mg/dl; p = 0.005) glucose concentrations during gestation were significantly greater in the patients with frank glucose intolerance as compared with the normal postpartum GTT group. Furthermore, all seven (100%) of the patients with frank glucose intolerance required insulin therapy during gestation as compared with 32 (40%) of the patients with normal postpartum glucose tolerance (p = 0.003). Stepwise logistic regression analysis was not used to determine which risk factors were most predictive of postpartum frank glucose intolerance because of the small number of subjects in this group.

Comment

The results of this study demonstrate that ar mately 20% of women with gestational diabeter have normal postpartum glucose tolerance

Table IV. Maternal data relating to glucose tolerance in 87 patients with normal glucose tolerance (n = 80) and frank glucose intolerance (n = 8) post partum

cluded women with impaired and nondiagnostic test results in our abnormal group because there is an increased risk for the development of type II diabetes mellitus in patients with impaired glucose tolerance,10 and the distinction between normal and impaired glucose tolerance (nondiagnostic category) is an arbitrary distinction on the far right end of the normal distribution curve of glucose values in nondiabetic subjects." Furthermore, when we analyzed the data from the seven patients with frank glucose intolerance in comparison with the patients with normal postpartum glucose tolerance, the most highly significant differences again were fasting glucose level, gestational age at the time of diagnosis of gestational diabetes, and the need for insulin therapy during gestation. We believe it is important to identify, as early as possible, all the women in these high-risk groups to institute long-term therapeutic recommendations for diet, activity, and achievement of ideal body weight.

The results of our study agree with those described by Kjos et al.⁷ They found a 19% (48/246) incidence of abnormal glucose tolerance in women with gestational diabetes in the early postpartum period. Furthermore, they also found that fasting glucose level and diagnosis of gestational diabetes before 24 weeks' gestation were additional risk factors for abnormal postpartum glucose tolerance.

Our study, however, differs from the previous study because of the different subject populations and definitions used to define glucose tolerance. Ninety-eight percent of the women examined by Kjos et al. in Los Angeles had Spanish surnames. Our subject population was predominantly white (82%), with lesser percentages of black and Hispanic subjects. There is a >15% rate of diabetes in Mexican-Americans 2 as compared with

the 5% to 7% prevalence of diabetes mellitus in whites.¹³ The difference in the prevalence of diabetes in the different study populations is potentially a confounding variable that needs to be considered when the results of the studies are compared.

The glucose concentrations that we used to define gestational diabetes were those of Carpenter and Coustan.⁸ In contrast, Kjos et al.⁷ used the criteria of the National Diabetes Data Group,⁹ which are approximately 6% higher than the glucose thresholds that we used. Hence, our subject population might be expected to include women with less severe glucose intolerance. Furthermore, we included women with nondiagnostic glucose tolerance in our abnormal group, whereas women with nondiagnostic postpartum glucose tolerance were classified as normal by Kjos et al.⁷ In spite of the differences in study populations and definition of glucose tolerance, both studies found that approximately 20% of women with gestational diabetes will have an abnormal postpartum glucose tolerance.

Forty-nine percent (51/103) of our study subjects required insulin therapy during gestation as compared with 15% to 20% in our overall gestational diabetic population. Hence, the patients most likely to complete postpartum glucose tolerance testing were those women who required more intensive therapy during pregnancy. Therefore the incidence of abnormal postpartum glucose tolerance may be lower if all women with gestational diabetes are tested.

As expected, there was a greater risk of an abnormal postpartum glucose tolerance in women with gestational diabetes who had many of the characteristics commonly associated with type II diabetes. They were significantly heavier and had a greater body mass index¹⁴ as compared with the women with normal post-

partum glucose tolerance. Furthermore, elevated fasting glucose level, gestational age at diagnosis, and insulin therapy were found to be the best predictors of abnormal postpartum glucose tolerance. These findings most probably represent either women with abnormal but unrecognized glucose intolerance before conception or women with more severe degrees of subclinical abnormalities of glucose metabolism made manifest by the stress of pregnancy.15 The pathophysiologic characteristics of these subclinical metabolic abnormalities (i.e., increased peripheral or hepatic insulin resistance, inadequate insulin response, or a combination of factors) that result in gestational diabetes or postpartum glucose intolerance have yet to definitively described. However, these results would further support early screening for gestational diabetes in women with multiple risk factors.

In summary, the results of this study support the recommendations of the Second International Workshop-Conference on Gestational Diabetes Mellitus⁶ that women with gestational diabetes have a postpartum oral GTT. Furthermore, women with elevated fasting glucose levels, diagnosis at an early gestational age, and possibly insulin therapy during pregnancy are at higher risk of having an abnormal GTT result. The early recognition and treatment of diabetes mellitus and abnormal postpartum glucose tolerance may help decrease the long-term morbidity and mortality in this high-risk population.

Urinary protein/creatinine ratio before and during pregnancy in women with diabetes mellitus

C. Andrew Combs, MD, PhD, Bernadette C. Wheeler, MD, and John L. Kitzmiller, MD San Francisco, California

Quantitation of urinary protein excretion has traditionally involved collection of a 24-hour urine specimen. Recent reports have suggested that the ratio of protein to creatinine in a single-voided urine specimen may be used as a screening test of proteinuria, obviating the need for a 24-hour urine collection. This study was undertaken to determine whether the urinary protein/creatinine ratio was correlated with 24-hour protein excretion in women with diabetes, to determine whether pregnancy had any effect on the correlation, and to test the accuracy of estimates of 24-hour protein excretion on the basis of the protein/creatinine ratio. We studied 329 24-hour urine specimens from 133 women with classes B through RF diabetes. The protein/creatinine ratio was highly correlated with total protein excretion (r = 0.977, p < 0.0001). The correlation was not affected by pregnancy, trimester, or preeclampsia. Three methods were used to predict protein excretion on the basis of the ratio. Compared with actual protein excretion, predicted values had mean errors of 19% to 27%; 6% to 13% of predictions were in error by $\geq 50\%$. Because of these large errors, we conclude that this method of estimating protein excretion has limited value in pregnant women with diabetes. (AM J Obstet Gynecol. 1991;165:920-3.)

Key words: Proteinuria, diabetes mellitus, pregnancy

Urinary protein excretion is routinely assessed before and during pregnancy in women with diabetes to detect nephropathy and to follow its course. Quantitation of protein excretion is also of value in the diagnosis of preeclampsia. Standard diagnostic criteria for diabetic nephropathy and preeclampsia are based on 24-hour urinary protein excretion. However, 24-hour urine collections are inconvenient for patients, and incomplete collections are common.¹

Recent reports have shown that the ratio of protein to creatinine in a single-voided urine specimen has an excellent correlation with the 24-hour urinary protein excretion, suggesting that this ratio might be a useful screening test of protein excretion. The correlation has been validated in healthy nonpregnant subjects, and renal disease, and pregnant women with and without pre-eclampsia. It has not been validated in pregnant women with diabetes.

This study was undertaken to determine whether the urinary protein/creatinine ratio was correlated with 24-

Andrew Combs, MD, PhD, Division of Maternal-Fetal Medicine (ML-526), University of Cincinnati College of Medicine, Cincinnati, OH 45267-0526. 6/6/30896 hour protein excretion in women with diabetes, to determine whether pregnancy had any affect on the correlation, and to test the accuracy of several methods of estimating 24-hour protein excretion on the basis the protein/creatinine ratio.

Methods

Records were reviewed from all women followed in the Diabetes and Pregnancy Program at Children's Hospital of San Francisco and Moffitt Hospital, University of California, San Francisco. Inclusion criteria were diagnosis of diabetes mellitus before pregnancy, enrollment before 16 weeks of gestation, and delivery from 1982 through 1989. Women with gestational diabetes were not included.

The protocol for management of diabetes in pregnancy included a 24-hour urine collection for measurement of total protein and creatinine clearance before pregnancy (if possible) and at or near the end of each trimester of pregnancy. Total protein was measured by the benzethonium chloride method⁷ or the Coomassie brilliant blue method⁸ and expressed in grams per day. Urinary creatinine (grams per day) was measured by the Jaffe reaction. Specimens were considered inadequate and were excluded from analysis if total creatinine excretion was <10 mg/kg/day or if there was evidence of bacteriuria. Protein/creatinine ratio (a unitless quantity) was calculated from the total protein and total creatinine values of each 24-hour specimen.

For the initial analyses, specimens were grouped ac-

Trimester	No.	Regression line	r	R^2	p Value
Prepregnant	35	$TP = 1.26 \times PCR - 0.03$	0.975	0.951	< 0.0001
First	109	$TP = 1.10 \times PCR + 0.03$	0.971	0.942	< 0.0001
Second	106	$TP = 1.12 \times PCR + 0.03$	0.995	0.989	< 0.0001
Third	79	$TP = 1.22 \times PCR - 0.02$	0.966	0.934	< 0.0001
Pooled data	329	$TP = 1.15 \times PCR + 0.02$	0.977	0.955	< 0.0001

r, Pearson product-moment correlation coefficient; TP, total protein excretion (grams per day), PCR, protein (grams)/creatinine (grams) ratio.

cording to trimester of collection. Within each group, the linear correlation between protein/creatinine ratio and 24-hour total urinary protein was calculated with least-squares regression. Between-group differences in the regression lines were tested with analysis of covariance, and between-group differences in total creatinine excretion were tested with repeated-measures analysis of variance. Because these analyses showed no significant differences, subsequent analyses were performed after the data from prepregnancy and all three trimesters were pooled.

Three methods for estimating 24-hour urinary protein excretion on the basis of the protein/creatinine ratio were evaluated. The first two methods were based on the formula:

Predicted
$$TP = PCR \times CREAT$$

where TP is 24-hour total protein excretion (grams), PCR is the protein/creatinine ratio (grams per gram, a unitless quantity), and CREAT is 24-hour total creatinine excretion (grams). In the first method total creatinine excretion was calculated from the formula of Cockroft and Gault10:

$$CREAT = [(140 - Age) \times (Weight) \times 0.85]/5000$$

where creatinine excretion is in grams per day, age is in years, and weight is in kilograms. In the second method 24-hour total creatinine excretion was taken as the observed mean value of 24-hour creatinine excretion (1.26 gm/day). The third method was based on the formula:

Predicted
$$TP = (PCR \times Slope) + Intercept$$
,

where slope is the slope of the pooled regression line relating the 24-hour total protein excretion to the protein/creatinine ratio (1.15 gm), and intercept is the y-intercept of that line (0.02 gm). For all three methods, the predicted value of the 24-hour total protein excretion was compared with its actual value using leastsquares regression and by calculating the mean percentage error and the fraction of predicted values of the 24-hour total protein excretion that differed from the actual value by >50%.

All statistical analyses were performed with SPSS.11 All p values < 0.05 were considered significant. Values are expressed as mean ± 1 SD.

Table II. Total creatinine excretion by trimester

Trimester	No.	Creatinine excretion (gm/day)		
Prepregnant	35	1.20 ± 0.24		
First	109	1.30 ± 0.28		
Second	106	1.27 ± 0.30		
Third	79	1.22 ± 0.31		
Pooled data	329	1.26 ± 0.29		

Data are mean \pm 1 SD.

Results

One hundred fifty-eight consecutive women met the inclusion criteria. Twenty-five women were excluded because they had no adequate urine collections. In the remaining 133 women there were 329 adequate specimens; 35 of these women had adequate collections before pregnancy.

Maternal age averaged 30.9 ± 5.0 years, and the average interval from diagnosis of diabetes was 12.5 ± 7.6 years. Fifty women were in White class B, 36 in class C, 18 in class D, 20 in class F, 6 in class R, and 3 in class RF. By the time of the third-trimester collection, 17 had preeclampsia, defined as a sustained increase in blood pressure > 140/90 mm Hg with proteinuria ≥ 300 mg/day.

Urinary protein/creatinine ratio was linearly correlated with 24-hour protein excretion before pregnancy and in all three trimesters. The regression statistics are summarized in Table I. Analysis of covariance showed no differences in the slopes or intercepts of the regression lines between the four groups, so the results were pooled to derive a final regression line. The pooled data are plotted in Fig. 1. The two panels show that the strong linear relation applied for high values of urinary total protein, as well as for low values. The presence of preeclampsia had no significant effect on the regression.

Table II shows the values of total creatinine excretion from before pregnancy and in all three trimesters. Analysis of variance showed no significant difference between the groups.

Table III compares the performance of the three methods for estimating 24-hour total protein excretion on the basis of the protein/creatinine ratio. The values of total protein predicted with the Cockroft-Gault for-

Table III. Accuracy of prediction of 24-hour protein excretion from protein/creatinine ratio

	,	Regression of precon actual T					
Method	Formula	Slope	Intercept	r	Mean error	Errors >50%	
Cockroft-Gault	$TP = PCR \times (140 - Age) (Wt) \times 0.85$ 5000	1.32	0.05	0.982	27% ± 31%	13% ·	
Mean creatinine Regression	$TP = PCR \times 1.26$ $TP = PCR \times 1.15 + 0.02$	1.09 1.00	$0.02 \\ 0.00$	$0.977 \\ 0.977$	$19\% \pm 20\%$ $24\% \pm 29\%$	6% 9%	

TP, Total protein (grams per day); r, Pearson product-moment correlation coefficient; PCR, protein (grams)/creatinine (grams) ratio; Age, maternal age (years); Wl, maternal weight (kilograms).

mula were strongy correlated with the actual values (r=0.981), but the slope of the regression line was 1.32, indicating that the formula overestimated protein excretion. As a result, predicted values differed from actual values by $27\% \pm 31\%$; indeed, 13% of the predicted values differed from the measured values by >50%. These errors occurred, in part, because measured total creatinine excretion was not significantly correlated with the creatinine excretion predicted by the Cockroft-Gault formula (r=0.097; p>0.05). Indeed, measured creatinine excretion was only weakly correlated with maternal age (r=0.129, p<0.02) or body weight (r=0.129, p<0.02).

The other formulas resulted in slightly smaller average errors between actual and predicted values, but both formulas resulted in a considerable fraction of patients in whom there was an error of >50% between measured and predicted values.

Comment

Because the method can be applied to a single-voided urine specimen, quantitation of urinary protein from

the protein/creatinine ratio has potential advantages over collection of a 24-hour specimen. In a prospective study, 35% of women who were asked to complete a 24-hour collection failed to provide an adequate specimen, either because of noncompliance or because of inadequate urine volume. The protein/creatinine ratio, in principle, is not dependent on urinary volume and can be applied to any random urine specimen. Further, the method does not impose a mandatory 24-hour delay to obtain a specimen, so that results can be immediately available. This may be useful in the management of preeclampsia, where rapid increases in urinary protein excretion may indicate a need to expedite delivery.

There are also some major disadvantages to the estimation of protein excretion on the basis of the protein/creatinine ratio. First, the standard diagnostic criteria for both diabetic nephropathy and preeclampsia are based on 24-hour protein excretion.^{12, 13} Because there are no accepted diagnostic standards that are based on protein/creatinine ratio, it is necessary to calculate a daily protein excretion from the ratio. Algebraically, this is accomplished by multiplying the ratio

by the 24-hour total creatinine excretion. However, unless a 24-hour specimen is collected for measurement of creatinine excretion, it is necessary to assume some value of creatinine excretion. In this study the predicted values of protein excretion that are based on the protein/creatinine ratio were highly correlated with the actual values (Table III), but all three methods yielded a considerable percentage with large errors. Thus values of daily protein excretion derived from protein/creatinine ratios must be regarded only as estimates.

Another disadvantage, not addressed by these data, is that both protein excretion and creatinine excretion have diurnal variations.14, 15 Because protein excretion is elevated by dietary protein and exercise, a urine specimen obtained late in the day may have a higher protein concentration than an overnight specimen. While there may be less day-to-day variability in first-morning voided specimens than in random specimens or 24hour specimens,5 first-morning specimens have poor sensitivity and specificity in the diagnosis of diabetic nephropathy and incipient nephropathy.15 Further, in preeclampsia protein excretion rates can vary from hour to hour,16 and thus a single-voided urine specimen may not accurately reflect average protein excretion.

Given these disadvantages, we believe that estimation of urinary protein excretion on the basis of the protein/creatinine ratio has limited value in pregnant women with diabetes. Two potential roles for this method are in patients who are noncompliant with 24hour urine collections or in patients with preeclampsia in whom the information is needed rapidly. However, even in these patients, it must be recognized that large errors in estimation can occur and it is not clear that the method is better than qualitative dipstick testing.

Drug abuse screening of childbearing-age women in Alabama public health clinics

Sherry K. George, MPA,^a Jan Price, MSN,^b John C. Hauth, MD,^b Doris M. Barnette, MSW,^a and Pete Preston, BS^a

Montgomery and Birmingham, Alabama

During August 1989, the urine of 5010 women of childbearing-age in Alabama was screened for marijuana, cocaine, opiates, amphetamines, and barbiturates. The data base consisted of 2970 pregnant women, 374 of whom were at high risk, and 2019 nonpregnant women. Our findings included the following information: (1) The statewide prevalence of positive screens for any drugs tested was 12.9% for all women (11.0% for those who were pregnant and 15.6% for those who were not pregnant). (2) There was no difference between urban and rural groups for any drugs tested. (3) Positive marijuana screens were increased among white and nonpregnant women (p < 0.01). (4) Positive cocaine screens were increased among black and single women (p < 0.01). (5) More screens were positive in women older than age 20 (p < 0.01). (6) There was no difference between pregnant and nonpregnant women for positive cocaine screens. (7) No difference existed among the trimesters of pregnancy for positive cocaine screens. (8) Positive screens for marijuana were more frequent in the first trimester of pregnancy than in the second trimester (p = 0.02) or the third trimester (p = 0.001). (9) There was no difference between high-risk and low-risk maternity patients for any drugs tested. (AM J OBSTET GYNECOL 1991;165:924-7.)

Key words: Drug abuse, prevalence

More than 5 million American women of childbearing age use illicit drugs. Almost 1 million of these women use cocaine, and 3.8 million use marijuana.¹ Numerous studies have examined known drug users or have assessed the effects of illicit drug use among pregnant women and their infants.²-⁴ However, we are not aware of any previous assessments of the statewide prevalence of drug use in pregnant and nonpregnant women of childbearing age.

This study was designed to determine the prevalence of illicit drug use among women enrolled in maternity and family planning clinics in Alabama and among women enrolled in a high-risk obstetric referral clinic.

Background

Alabama is classified as an urban state with scattered rural areas.⁵ Public health maternity services are available in all counties for pregnant women with incomes

From the Alabama Department of Public Health^a and the Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, University of Alabama at Birmingham.^b

This study was conducted in Alabama public health clinics.

Funds were provided by the Alabama Department of Public Health, the Alabama Medicaid Agency, and the Alabama Department of Mental Health and Mental Retardation. Equipment was supplied by Abbott Laboratories.

Presented at the Eleventh Annual Meeting of the Society of Perinatal Obstetricians, San Francisco, California, January 28-February 2, 1991.

Reprint requests: Sherry K. George, MPA, Alabama Department of Public Health, 434 Monroe St., Montgomery, AL 36130-1701. 6/6/30773 below 150% of the federal poverty level. Maternity patients are screened for risk factors at each visit. Family planning services are available to anyone but were developed for women with incomes below 150% of the federal poverty level.

Most patients referred to the Division of Maternal-Fetal Medicine Obstetric Complications Clinic (OBCC) of the University of Alabama at Birmingham are from public health maternity clinics. In the OBCC patients are grouped into three areas: high-risk or intermediaterisk obstetric complications, prematurity prevention, or hypertension prevention.

Methods

Our study population consisted of pregnant and nonpregnant women enrolled in public health maternity and family planning clinics or in the OBCC at the University of Alabama at Birmingham. A nonexperimental descriptive research design was used. Urine samples from anonymous patients were tested for marijuana, cocaine metabolites, opiates, amphetamines, and barbiturates. Subject consent was not obtained. It was assumed that positive findings for any of the drugs indicated illicit use.

Urine samples and corresponding demographic data were collected from Aug. 21, 1989, to Sept. 1, 1989. Urine samples obtained for routine testing procedures at each patient visit were used. At the usual point of discard, excess urine from each sample was poured or injected into a plain red Vacutainer blood collection tube. The tubes were one-half to three-quarters filled,

and the stoppers were secured with tape if the injection method was not used. No identifying information was placed on the tubes. As the samples were obtained, each patient's chart was marked with an identifier (sticker). Thus no duplicate samples were submitted. Demographic data were obtained from a review of the patients' charts, but no identifying information was included. All urine samples and demographic data forms were sent to the state laboratory in Montgomery, Alabama.

Drug screening for amphetamine or methamphetamine, barbiturates, cannabinoids, cocaine metabolites, and opiates was performed by means of a fluorescence polarization immunoassay. All positive samples underwent a second analysis. The manufacturer's recommended cutoff levels for determining the presence of drugs and drug metabolites were used to report the results. The manufacturer claims 99% to 100% agreement with gas chromatography—mass spectrometry for positive specimens and 95% to 100% agreement for negative specimens. Because many over-the-counter drugs produce metabolites that mimic amphetamine and methamphetamine, positive specimens in this category were re-tested with thin-layer chromatography. Only the amphetamine-confirmed specimens were in-

cluded as positives. No further confirmatory testing was performed on positive specimens in the other drug categories. We specifically wished to evaluate the prevalence of illicit drug use among rural and urban populations, among white and black populations, among single and married women, in relation to age, among pregnant and nonpregnant women, in relation to parity and current pregnancy, in relation to the trimesters of pregnancy, in a high-risk referral obstetric clinic population compared with a low-risk referral obstetric clinic population (women enrolled in research-oriented clinical trials), among women referred to a high-risk obstetric clinic because of a history of substance abuse who were compared with those referred for other complications, and among high-risk obstetric referral patients compared with the low-risk public health maternity population from the same urban county.

After laboratory analysis, all patient demographic data were entered into a computer by means of Professional File (Software Publishing Corp., Mountain View, Calif.). All computations (percentages, measures of central tendency [means], and measures of dispersion [standard deviations]) were computed with Lotus. Data results were computed with χ^2 analysis and Fisher's exact test.

^{*}Subgroup of pregnant population.

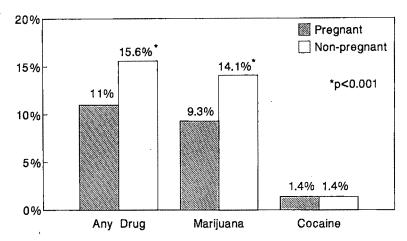

Fig. 1. Statewide prevalence of illicit drug use by pregnancy status.

Results

Statewide population. Six hundred forty-six patients (12.9%) tested positive for at least one of the drugs (Table I). Specifically, 11.3% tested positive for marijuana, 1.4% for cocaine, 0.6% for barbiturates, 0.4% for opiates, and 0.3% for amphetamines.

In the 646 women with positive screens, the drug most frequently used was marijuana (87.5%), which was followed by cocaine (10.7%), barbiturates (4.8%), opiates (3.1%), and amphetamines (2.0%). Fifty-two women (12.4%) tested positive for two or more of the drugs. Of the women who had multiple positive screens, 41 (78.8%) tested positive for cocaine and marijuana.

Various demographic characteristics of the group that had positive drug screens are presented in Table I. Positive screens for any drug and for marijuana were higher in white women, who were two times more likely to test positive for any drug or for marijuana than were black women (p < 0.001). Black women were 2.1 times more likely to test positive for cocaine than were white women (p < 0.003). The use of any drug or marijuana or cocaine was more frequent in women older than age 20 than in teenagers (p < 0.001). The mean age of women who tested positive for any drug was 23.8 years (SD, +4.93).

Single women were 2.6 times more likely to test positive for cocaine than were married women (p < 0.002). There was no difference in the marital status of women who tested positive for any drug or for marijuana. Multiparous women had significantly more positive screens for any drug and for marijuana than did nulliparous or primigravid women (p < 0.001); however, there was no significant difference in positive cocaine screens among these groups. The urban-rural distribution was similar among women who tested positive for any of the drugs.

Of the 2970 pregnant women screened, 326 (11.0%) tested positive for at least one of the drugs, as compared with 315 (15.6%) of the 2019 nonpregnant women

screened. Nonpregnant women were 1.5 times more likely to have a positive screen for any drug or for marijuana than were pregnant women (p < 0.001). Pregnant and nonpregnant women had a similar prevalence of positive cocaine screens (Fig. 1). Among statewide pregnant women, positive screens for marijuana were more frequent in the first trimester of pregnancy than in the second trimester (p = 0.02) or the third trimester (p = 0.001). The frequency of positive cocaine screens was similar in each trimester. Overall, the highest percentages of positive cocaine screens occurred in the urban areas of Mobile and Birmingham (2.2% and 2.1%, respectively).

Obstetric referral high-risk population. Forty-five (12%) of the 374 OBCC patients screened tested positive for at least one of the drugs. Forty (14.2%) of the 282 women enrolled in the high-risk or intermediaterisk obstetric complications clinics or the prematurity prevention clinic had a positive urine screen. A positive screen was seen in only 7 (7.6%) of the 92 women enrolled in the low-risk Hypertension Prevention Project (p = 0.098, NS).

Fifteen (4%) of the 374 OBCC patients tested were referred because of a history of alcohol and/or drug abuse. Eleven of these 15 (73%) had a positive drug screen; two of these 11 tested positive for more than one drug. Conversely, 26 (9.6%) of the women with a complication of pregnancy other than drug abuse (n = 267) had a positive urine screen (p < 0.001).

A total of 1104 maternity patients were screened in urban Jefferson County–Birmingham. In this county women enrolled in the OBCC had a frequency of positive urine screens (30/220) similar to that found among women considered to be at low-risk (88/884; p=0.11, NS).

Commen

Drug use is known to be common among pregnant women in the United States. The Rhode Island Department of Public Health found that 7.5% of women

in labor tested positive for at least one illicit drug.7 In Pinellas County, Florida,8 it was found that nearly 15% of the pregnant women studied tested positive for alcohol and drug use (12.0% tested positive for marijuana and 3.4% were positive for cocaine).

Our report provides a view of illicit drug use among pregnant and nonpregnant women aged 15 to 44 years in a statewide public health population. The prevalence of overall illicit drug use and marijuana use was higher in white women than in black women. However, black women were almost twice as likely to test positive for cocaine. The increased use of cocaine in black pregnant women is similar to that reported from Rhode Island and Florida. We found no difference between urban and rural populations for any of the drugs tested. Chasnoff⁹ found that the prevalence of drug use (particularly cocaine) in pregnancy was similar in different geographic areas of the country, regardless of the hospital or the size of the population studied.

In a congressional hearing, Ja Joon testified that "cocaine-using mothers typically are not first-time, adolescent mothers, but older women, who do not plan for their pregnancies."10 We confirmed a significantly higher prevalence of cocaine use (as well as use of any drug or marijuana) among women >20 years old. We also found that the use of any drug was significantly higher among women who had one or more children.

Our pregnant and nonpregnant populations were similar with respect to the frequency of a positive urine screen for cocaine (1.4%). Of the drugs targeted in our study, the potential adverse effects of cocaine use during pregnancy are best known. However, the potential for pregnancy complications and/or poor perinatal outcomes is increased when any of these drugs is abused.11-15 Thus we surmised that women identified as having high-risk pregnancies may have a higher prevalence of illicit drug use than do women who are considered to have low-risk pregnancies. Our results did not support this hypothesis. A higher prevalence of illicit drug use was found only among those who were referred to the OBCC because of a known drug abuse

Our report was limited to randomly selected women from the public health sector who were seen during a specific 2-week period. Women from the private sector were not screened. The assignment of urban or rural status was based solely on population density. Per capita income and economic activity were not considered. Urine screening has a short half-life. Thus, because serial testing was not performed, it is possible that the total drug exposure of fetuses may have been substantially underestimated in this population.

This article is dedicated to the memory of Sue Jones, who so graciously spent many hours computing the data for this project. Other individuals acknowledged for their contributions to this paper are Dr. Bruce Harris and Dr. Charles Woernle, editorial review; Fern Shinbaum, Lee Rawlinson, and Jim Laney, study development; and Sue Cliver, statistical analysis.

Shoulder dystocia and birth trauma in gestational diabetes: A five-year experience

James D. Keller, MD, Jose A. Lopez-Zeno, MD, Sharon L. Dooley, MD, and Michael L. Socol, MD

Chicago, Illinois

Over a 5-year period, 210 patients with gestational diabetes mellitus were delivered of offspring weighing ≥3500 gm. Only three primary cesarean sections were performed electively because of suspected macrosomia. One hundred twenty patients were delivered vaginally. There were 15 shoulder dystocias but only one permanent brachial plexus injury. Seven of the 15 shoulder dystocias occurred in offspring weighing <4000 gm. Of variables examined, only the use of forceps was clearly associated with an increased risk of shoulder dystocia (odds ratio, 5.1). A policy to deliver by cesarean section all fetuses estimated to weigh >4000 gm would considerably increase the number of cesarean sections with minimal fetal benefit. (AM J OBSTET GYNECOL 1991;165:928-30.)

Key words: Shoulder dystocia, birth trauma, gestational diabetes

Shoulder dystocia is a potentially serious complication in pregnancies complicated by diabetes mellitus¹ and has been noted in 13% to 31% of pregnancies with an infant weighing ≥4000 gm.². ³ These observations have led some to recommend elective cesarean section for diabetic patients when the estimated fetal weight is >4000 gm.².⁴ Inherent problems with this scheme are the inaccuracies in estimation of fetal weight and the maternal morbidity associated with cesarean section.⁵ Additionally, it is uncertain whether the risk of shoulder dystocia is as high in gestational diabetes mellitus as it is in pregestational insulin-dependent diabetes mellitus, and most studies have used a heterogeneous population of both to generate clinical recommendations.².⁴

Because of these issues we have adopted a liberal philosophy in patients with gestational diabetes mellitus, encouraging an attempt at vaginal delivery as long as labor progresses normally and discouraging primary cesarean sections for the sole indication of an estimated fetal weight >4000 gm. This philosophy permitted us to examine the frequency of shoulder dystocia and birth trauma in a large population of patients with gestational diabetes mellitus allowed a trial of labor.

Material and methods

Between Oct. 1, 1983, and July 30, 1989, 210 patients with gestational diabetes mellitus whose neonates

From the Section of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, Northwestern University School of Medicine. Presented at the Eleventh Annual Meeting of the Society of Perinatal Obstetricians, San Francisco, California, January 28–February 2, 1991.

Reprint requests: James D. Keller, MD, 1875 Dempster, Suite 325, Park Ridge, IL 60068. 6/6/30771 weighed ≥3500 gm were identified by means of the Prentice Women's Hospital perinatal data base. During this time period, women obtaining prenatal care underwent universal screening for gestational diabetes mellitus. The diagnosis was established with the O'Sullivan-Mahan criteria modified for plasma glucose.6 Patients who remained normoglycemic on diet therapy were denoted A₁ gestational diabetes mellitus. If fasting plasma glucose level exceeded 105 mg/dl or the postprandial plasma glucose was elevated (1 hour, >140 mg/dl), the patient was denoted A2 gestational diabetes mellitus, and insulin therapy was initiated unless the patient was ≥36 weeks' gestation. Patients with a fasting plasma glucose level ≥130 mg/dl were excluded from this study because of the likelihood that these patients had unrecognized pregestational diabetes.

The following variables were examined: severity of maternal carbohydrate intolerance, parity, use of oxytocin for augmentation of labor, length of second stage of labor, mode of delivery, birth weight, occurrence of shoulder dystocia, and presence or absence of birth injury. Shoulder dystocia was diagnosed by the physician attending the delivery. Follow-up of offspring discharged from the hospital with a brachial plexus injury was obtained from either the parent or pediatrician of the injured neonate.

Statistical analysis was performed by Student t test for means of continuous variables. Odds ratios were calculated for discrete data with 95% confidence intervals.

Results

Of the 210 mother-infant pairs, 173 underwent a trial of labor. Three patients were delivered by primary cesarean section because of suspected macrosomia before

Forceps	8	4 (50%)		

onset of labor (actual birth weight, 3800, 3880, and 4460 gm); both infants weighing <4000 gm were estimated by ultrasonography to be >4000 gm (4388 and 4436 gm, respectively). Thirty-four patients had elective repeat cesarean sections. The mode of delivery for the remaining 173 patients is shown in Table I. (Eight of 13 attempts at vaginal birth after cesarean section were successful with no occurrences of shoulder dystocia.)

The incidence of shoulder dystocia and birth trauma in the 120 patients who ultimately were delivered vaginally is illustrated in Table II. Of the four brachial plexus injuries, two resolved before discharge from the hospital, and one resolved by I month of age. One infant (birth weight, 4220 gm) continues to show mild residual impairment 4 years after delivery.

The birth weight was greater, but not significantly

different, in deliveries complicated by shoulder dystocia (4094 ± 517 vs 3933 ± 317 gm, respectively; p = 0.08). As can be seen in Table III, in those patients delivered vaginally neither A_2 gestational diabetes mellitus, use of oxytocin for augmentation of labor, nor nulliparity increased the risk of shoulder dystocia. Use of forceps, however, did increase the risk of shoulder dystocia (birth weights, 3700, 4100, and 4135 gm) approximately fivefold. Prolonged second stage of labor (>60 minutes in multiparous women, >120 minutes in primiparous women) was associated with a trend toward an increased risk of shoulder dystocia (odds ratio, 2.36; 95% confidence interval, 0.55 to 7.98).

Comment

In spite of continued improvement in perinatal outcome in gestational diabetes, shoulder dystocia and sub-

sequent birth trauma remain serious complications. It is known that offspring of diabetic mothers are at greater risk of shoulder dystocia than are the offspring with similar birth weights of normoglycemic women. This is believed to be due to proliferation of insulinsensitive tissue that causes a relative disproportion in the size of the fetal chest and shoulders relative to the fetal head.7 Acker et al.,2 in a restrospective review of shoulder dystocia, reported a 31% incidence in deliveries involving maternal diabetes and a birth weight >400 gm. No distinction was made between those with gestational diabetes mellitus versus insulin-dependent diabetes mellitus. In our series shoulder dystocia occurred less frequently (8 of 45 vaginal deliveries with birth weight ≥4000 gm). This may reflect differing clinical criteria for the diagnosis of shoulder dystocia, a problem inherent in comparing retrospective studies. Alternatively, there may be a lower incidence of shoulder dystocia in gestational compared with insulin-dependent diabetes mellitus.

Our study failed to show that more severe carbohydrate intolerance (A₂ gestational diabetes mellitus), use of oxytocin, or nulliparity increased the risk of shoulder dystocia. There was a trend toward an increased risk of shoulder dystocia when the second stage of labor was prolonged, but the only significant increase occurred in vaginal deliveries accomplished by forceps. Replacing forceps delivery with cesarean section would have reduced shoulder dystocia by >25%. On the basis of our findings, forceps should be used with caution in pregnancies complicated by gestational diabetes mellitus when the birth of a large infant is anticipated.

Several strategies have been suggested to reduce the risk of shoulder dystocia in diabetes, including the liberal use of cesarean section.^{2,4} If perfectly executed, a

protocol to deliver every fetus >4000 gm by cesarean section would have increased the number of nonelective cesarean sections from 53 to 98 in our series. This excess of 45 cesarean deliveries would have obviated eight of 15 shoulder dystocias and one permanent brachial plexus injury. Although one could argue that such an approach is justified on the basis of the serious nature of the pediatric injury, it would not be possible to perfectly execute such a protocol in that there are serious limitations to the accurate estimation of fetal weight. Furthermore, almost half the instances of shoulder dystocia and birth trauma occurred in offspring weighing <4000 gm. Consequently, we continue to believe that to deliver by cesarean section all fetuses estimated to weigh >4000 gm would considerably increase the number of cesarean sections performed but not eliminate the risk of shoulder dystocia.

Administration of heparin by subcutaneous infusion with a programmable pump

Randall C. Floyd, MD, Kathy S. Gookin, MSN, L. Wayne Hess, MD, Rick W. Martin, MD, Keith F. Rawlinson, MD, Ramona K. Moenning, RN, and John C. Morrison, MD *Jackson, Mississippi*

Heparin has a short half-life (8 to 12 hours) and therefore must be administered by continuous infusion or by intermittent subcutaneous injection. Intermittent subcutaneous injection may lead to fluctuation in the levels of anticoagulation attained. In correcting this deficiency, the programmable automated subcutaneous infusion pump in conjunction with weekly home nursing visits has been used. Eight pregnant women with documented deep venous thrombosis or embolic events before pregnancy who received such therapy were studied. Eight similar subjects who received intermittent subcutaneous injection, matched for age, parity, site of deep venous thrombosis, and days on a regimen of heparin therapy, served as the control group. The mean daily dose of heparin by subcutaneous infusion pump was higher (29,445 vs 13.822 U). resulting in smoother, more therapeutic heparinization (mean partial thromboplastin time, 20.6 vs 10.4 seconds above control) when compared with the intermittent subcutaneous injection group (p < 0.05, $\rho < 0.007$). There were two complications (hematoma, site infection) in the intermittent subcutaneous injection group while none occurred in the subcutaneous infusion pump group. When used in concert with weekly home visits, the subcutaneous infusion pump method of administration allowed more even control of anticoagulation, appeared to result in fewer complications (although not statistically significant), and subjectively was better received by patients than the intermittent subcutaneous injection technique. (Am J OBSTET GYNECOL 1991;165:931-3.)

Key words: Deep venous thrombosis, anticoagulation, programmable external infusion pump

Deep venous thrombosis with subsequent pulmonary embolism is diagnosed with increased frequency during pregnancy.^{1,2} The incidence of deep venous thrombosis complicating gestation ranges from 0.05% to 1.8% and is most common after cesarean birth (2.2% to 3%). Its occurrence after vaginal birth is less frequent (0.5% to 1.2%). History of a thromboembolic complication, particularly if it occurred during a prior gestation, is considered to increase the risk of such problems in the current pregnancy to approximately 12%.4 Pulmonary embolism occurs in up to 16% of patients with untreated deep venous thrombosis, yielding a mortality rate of approximately 15%.1, 2, 5 Anticoagulation, if the drug is appropriately administered, will reduce the risk of pulmonary embolism and subsequent risk of mortality to 0.7%.4

Anticoagulation therapy in ambulatory patients usually employs warfarin, a drug contraindicated during

From the Department of Obstetrics and Gynecology, University of Mississippi Medical Center.

gestation because of its teratogenic effects. Therefore parenteral administration of sodium heparin has been used on an outpatient basis as treatment for the pregnant patient. Heparin use is not without risk; hematomas, hemorrhage, hypersensitivity, alopecia, osteoporosis, and thrombocytopenia have been reported. 7-10

Heparin is usually administered in ambulatory patients by intermittent subcutaneous injection that involves two to four injections daily of 5000 to 10,000 U each. This therapy involves multiple injections that the patient may find objectionable, leading to diminished compliance. This method of administration also is associated with fluctuation of the level of anticoagulation. To address patient compliance and comfort many physicians reduce the number of injections per day, a practice that may result in inadequate anticoagulation.

In an effort to cope with these problems, it has been suggested that heparin be administered by continuous subcutaneous infusion with a programmable pump. ¹¹ Theoretically, this would allow for a more consistent, therapeutic level of anticoagulation while obviating the patient's need to perform multiple self-injections.

The purpose of the current study was to evaluate the use of the new automated programmable external infusion pump (model 404-SP, MiniMed Technologies,

Sylmar, Calif.) in an effort to achieve adequate anticoagulation in patients with thromboembolic disease.

Material and methods

A retrospective, paired, case-controlled study of 16 women was undertaken to evaluate the efficacy and complications from the automated external infusion pump for heparin infusion during pregnancy. Over a 9-month period, 8 patients were treated with the automated external infusion pump with comparison of their results to those of 8 women who were managed with intermittent subcutaneous injections of heparin during pregnancy. The patients were matched for age, parity, race, risk factor, and gestational age at onset of therapy. Patients managed with self-administered, intermittent, subcutaneous injections of heparin were treated every 8 to 12 hours utilizing standard dosing techniques.1 Patients who self-administered heparin were seen once per week in the physician's office to monitor coagulation parameters and assess the progress of the pregnancy.

The MiniMed model 404-SP external infusion pump with the MiniMed Soft Set (registered trademark of MiniMed Technologies) subcutaneous infusion set was used to administer the subcutaneous infusion of heparin in the treatment group. These patients were monitored by a perinatal nurse (Tokos Medical Corp., Santa Ana, Calif.) twice weekly with home visits for the first 2 weeks of the infusion. They received weekly home visits and prenatal visits to the physician each week for the remainder of the pregnancy. Perinatal nurses were available by telephone 24 hours per day. The patients in the subcutaneous infusion group were instructed in

self-management of the pump, as well as in needle insertion and care of the infusion site.

All subjects were monitored weekly with partial thromboplastin time determinations and complete blood counts. They were all counseled regarding signs and symptoms of complications. These included instructions to monitor urine color, to note any change in heart rate or feeling of vertigo, to report any signs or symptoms of infection at the injection site, and to report any unexplained bruising, multiple petechiae, or any bleeding that was difficult to stop.

Statistical analysis was performed with Barlett's test for homogenity of group variances performed for gestational age at onset and discontinuation of therapy, the amount of heparin infused per day, days of therapy, and measured partial thromboplastin times. Paired t tests were performed to evaluate the significance of differences, and Fisher's exact test was used to compare the complication rates in both groups. A p value of <0.05 was considered significant.

Results

As shown in Table I, comparison of the demographic characteristics such as age, race, parity, and diagnosis necessitating heparin therapy revealed no significant differences between the two groups. The gestational age at onset of therapy and total days of treatment also were not significantly different (Table II). These data reveal that the amount of heparin infused per day was significantly increased in the continuous infusion group (p < 0.05). The mean partial thromboplastin times noted in the continuous infusion group (20.6 ± 7.1) seconds) compared with the intermittent injection

group (10.4 ± 6.0 seconds) were significantly increased (p < .007).

The sites of administration in the continuous infusion group were rotated primarily between the abdomen and anterior thigh; 3 of the 8 patients used the deltoid region of the arm. No major complications were noted in the continuous infusion group; however, ecchymoses were reported in three patients, a small hematoma occurred in one woman, and oozing from the infusion site was seen in one subject. A nonpersistent epistaxis was noted in one patient who had noted ecchymosis. None of these complications was believed to be significant enough to cause discontinuation of therapy. The intermittent subcutaneous injection group was noted to have multiple episodes of minor side effects and two major complications—one injection site abscess and one large hematoma (Table II). The complication rates did not reach statistical significance, and no patient in either group experienced a recurrent embolic event.

Comment

Anticoagulation therapy by continuous subcutaneous infusion via external infusion pump appeared to be both safe and effective in this small group of patients. The successful use of this mode of administration is not consistent with the findings of the study performed in 1985 by Barss et al.11 In that study six patients received continuous subcutaneous infusion to reach a therapeutic partial thromboplastin time of 1.5 to 2.0 times control values. There were no recurrent thromboses, but five of the six patients experienced major or minor bleeding complications. This disparity may be secondary to a difference in infusion pumps used or type of infusion set. The infusion set used in this study did not involve an indwelling needle. Also, reliability, accuracy, and safety of the new infusion pump have been improved, compared with the unit used in the earlier study. Finally, the home nursing visits and intensive patient education may have played an important role in the different outcomes noted in the current study.

The significantly increased amount of heparin infused in patients by means of the infusion pump, noted in Table II, provided more adequate anticoagulation as measured by mean partial thromboplastin time. The improved anticoagulation profiles were obtained in these patients without an increase in serious morbidity. A central reason for these salutary results may be increased patient compliance. As previously noted, the

compliance rate of women using intermittent subcutaneous injection has been noted to be poor in previous studies.1, 2, 4 Patient acceptance of the soft catheter (vs the indwelling needle) and the reduced number of injections has been excellent in the patients who have used the continuous infusion pump. The increased cost of the subcutaneous infusion pump when compared with intermittent subcutaneous injection may be justified by these findings, which should lead to improved

Administration of heparin with the continuous subcutaneous infusion pump may be helpful not only in the context of heparin treatment for thromboembolism-related disorders but also for other complications necessitating anticoagulation during pregnancy. These indications include patients with atrial fibrillation, prosthetic heart valves, or valvular disease with a history of systemic emboli. 12, 15 The treatment regimen as outlined in this study appears to offer successful, safe, and efficacious anticoagulation and warrants further evaluation in pregnancy.

Placental pathologic findings in preterm birth

C.M. Salafia, MD, C.A. Vogel, MD, A.M. Vintzileos, MD, K.F. Bantham, MD, J. Pezzullo, PhD, and L. Silberman, MD

Danbury and Farmington, Connecticut, and Providence, Rhode Island

Microscopic features of placentas from 539 consecutive preterm deliveries and 214 term deliveries were compared. The presence of either umbilical or chorionic vasculitis was identified in 38% of the cases at 22 to 28 weeks' gestation, in 32% of the cases at 29 to 32 weeks' gestation, in 13% of the cases at 33 to 36 weeks' gestation, and in 10% of the cases at term (p < 0.0001). Decidual vascular abnormality was present in 70% of the cases at 22 to 28 weeks' gestation, in 35% of the cases at 29 to 32 weeks, in 29% of the cases at 33 to 36 weeks, and in 15% of the cases at term (p < 0.0001). Chronic villitis was significantly more frequent in preterm deliveries without umbilical vasculitis than in those cases with umbilical vasculitis (17% vs 8%, p < 0.05). Our data indicate that the placental lesions of umbilical-chorionic vasculitis, decidual vascular abnormality, and chronic villitis are related to preterm birth. Umbilical-chorionic vasculitis reflects acute ascending bacterial infection. Decidual vascular abnormality has been associated with maternal autoimmune or alloimmune disorders. Chronic villitis may indicate either congenital viral infection or maternal-fetal immunopathologic conditions. Both decidual vascular abnormality and chronic villitis may reflect the activation of inflammatory mechanisms capable of leading to preterm delivery. (Am J Obstet Gynecol 1991;165:934-8.)

Key words: Preterm delivery, vasculitis, villitis, placental pathologic findings

Preterm birth remains the primary cause of perinatal morbidity and mortality in this country.1 Certain maternal risk factors have been identified, such as multiple birth, incompetent cervix, lack of prenatal care, low socioeconomic status, and history of past preterm birth, but the mechanism by which they predispose to premature delivery is generally either unknown or related to an increased risk of ascending intrauterine infection.2 Our study was undertaken to search for placental pathologic processes that are significantly related to preterm birth and might provide clues to mechanisms for preterm birth. Acute ascending infection has been associated with increased incidence of prematurity, via mechanisms related to bacterial induction of cytokine and prostanoid production.2 Chronic immunologic or inflammatory conditions could elicit preterm labor via mechanisms similar to those proposed in cases with acute ascending infection. We hypothesized that placental lesions reflecting such chronic inflammatory processes are associated with prematurity. Chronic villitis, a chronic inflammation of the placental villi, indicates either congenital viral infection or maternal-fetal immunologic abnormality.³ Pathologic changes of the decidual vessels also have been suggested to have a basis in maternal autoimmune or alloimmune abnormality.⁴ Chronic intrauterine inflammation based at the level of either villus or decidua may alter collagen production by fibroblasts,⁵ leading to an increased likelihood of premature rupture of membranes. Finally, aberrant maternal-fetal immune interactions in the implantation site may lead to decidual vascular abnormality and an increased incidence of abruptio placentae.

To test this hypothesis, relationships between histologic evidence of acute ascending (bacterial) infection, chronic villitis, decidual vascular abnormality, and other disorders of the uteroplacental interface were examined in 539 cases of preterm birth and compared with findings in a control population of 214 spontaneous deliveries at term.

Material and methods

Between July 1983 and October 1990, all placentas from pregnancies delivered at <37 weeks' gestation at the Danbury Hospital were submitted for gross and microscopic examination by a single pathologist (C.M.S.). Cases of multiple gestation, stillbirth, congenital anomaly, maternal diabetes mellitus, preeclampsia, chronic hypertension, and elective delivery for indications such as ultrasonographically diagnosed intrauterine growth retardation were excluded from the consecutive series, yielding 539 cases of preterm birth. These included 241 cases of preterm labor, 94 cases of premature rupture of membranes, and 103 cases with

history of both preterm labor and premature rupture of membranes. A clinical history of abruptio placentae was present in 65 cases, including 25 cases in which the patients presented in preterm labor. During the same period, 214 spontaneous vaginal deliveries at term in which placental abnormality also occurred were chosen at random and used as a control population. These included two cases with a history of preterm labor, 34 cases of rupture of membranes prior to the onset of labor, and two cases with a clinical history of abruptio placentae, for a total of 38 of 214 cases (18%).

Placental examination was performed according to a modification of Benirschke's method.6 Placentas were weighed after removal of adherent blood and umbilical cord. Presence, number, and estimated volumes of infarctions were recorded and gross diagnoses were confirmed microscopically. Placental infarction was defined microscopically as a lesion in which trophoblast, stroma, and vessels were uniformly necrotic. Placental infarct(s) were defined as gross lesions that were typically wedge shaped and based on the maternal surface. Four sections of grossly normal placenta were examined for the presence of chronic villitis.7,8 For the purpose of this study, the presence of chronic villitis was graded as absent or present. The presence of umbilical and chorionic vasculitis was determined by examining two sections of the umbilical cord and at least one section of chorionic plate including three chorionic vessels. The presence of umbilical-chorionic vasculitis was used as the discriminator between cases with and without a significant acute ascending infection. Decidual vascular abnormality included any of the following: decidual thrombosis, lack of physiologic change or fibrinoid necrosis of decidual vessels, and chronic decidual vasculitis involving vessels of the implantation site. This chronic inflammatory lesion is easily distinguished from the acute vasculitis associated with ascending bacterial infections by the nature of the inflammatory infiltrate (chronic mononuclear vs acute polymorphonuclear) and its location (basal plate vs parietal decidua). Decidual vessels were searched for in the four random sections of the placenta. If decidual vessels were not identified, these cases were excluded from pertinent analyses, and determinations of significance regarding the association of decidual vascular abnormality with preterm birth were made with the subgroups of those cases in which the decidual vessels were able to be assessed. Specifically, the number of cases in which decidual vessels were not able to be assessed was as follows: at the gestational age of 22-28 weeks, 3 of 26 cases (11.5%); at 29 to 32 weeks, 15 of 92 cases (16%); at 33 to 36 weeks, 49 of 421 cases (11.6%); and at 37 to 42 weeks, 0 of the 214 cases. The diagnosis of abruptio placentae was made by any or all of the following pathologic findings: adherent retroplacental clot or placental de-

pression and microscopic changes including disruption of basal plate with decidual necrosis and villous infarct, focal villous stromal hemorrhage, focal villous edema, and trophoblast basophilia. It is recognized that clinical abruptio placentae, histologically reflects a premature placental separation, and the pathologic diagnosis of such a process in the delivered (and completely separated) placenta is problematic. For the purposes of this study, the broadest set of pathologic criteria was used.

Gestational ages were calculated from the last menstrual period with modification by data provided by early ultrasonography or by ultrasonographic estimate alone when menstrual dates were uncertain. For the purpose of data analysis, gestational ages were grouped as 22 to 28 weeks, 29 to 32 weeks, 33 to 36 weeks, and term. Contingency tables examined the associations of placental pathologic condition and gestational age. The contributions of umbilical-chorionic vasculitis, chronic villitis, and decidual vascular abnormality to preterm birth were considered significant at p < 0.05.

Results

The incidences of the clinical presentations in the preterm and control population are presented in Table I. History of preterm labor, premature rupture of membranes, and/or abruptio placentae was identified in all of 26 cases (100%) at 22 to 28 weeks, 87 of 92 cases (95%) at 29 to 32 weeks, 367 of 421 (87%) cases at 33 to 36 weeks, and 38 of 214 (18%) at 37 to 42

The incidences of umbilical-chorionic vasculitis, chronic villitis, and decidual vascular abnormality throughout gestation are presented in Table II and Fig. 1. Umbilical-chorionic vasculitis was observed in 10 of 26 (38%) of deliveries between 22 and 28 weeks' gestation, 29 of 92 (32%) between 29 and 32 weeks' gestation, 54 of 420 (13%) between 33 and 36 weeks' gestation, and 22 of 214 (10%) between 37 and 42 weeks' gestation. The association of umbilical-chorionic vasculitis with lower (earlier) gestational age was highly significant (p < 0.0001).

Chronic villitis was observed in 1 of 26 (4%) deliveries between 22 and 28 weeks' gestation, 8 of 92 (9%) between 29 and 32 weeks' gestation, 67 of 421 (16%) between 33 and 36 weeks' gestation, and 51 of 214 (23%) between 37 and 42 weeks' gestation. Chronic villitis was significantly more frequent in preterm cases without umbilical-chorionic vasculitis than in those cases with umbilical vasculitis (71/445 [16%] vs 5/93 [5%], p < 0.01).

Decidual vascular abnormality was observed in 16 of 23 (70%) deliveries between 22 and 28 weeks' gestation, 27 of 77 (35%) between 29 and 32 weeks' gestation, 107 of 372 (29%) between 33 and 36 weeks' gestation, and 33 of 214 (15%) between 37 and 42 weeks' gestation

Decidual vascular abnormality ($p = 0.0001$)	16/23	70	27/77	35	107/372	29	33/214	15

^{*}Decidual vessels could not be identified in all cases.

(p < 0.001). To test for independence of effects of umbilical-chorionic vasculitis and decidual vascular abnormality, contingency tables according to Fisher's exact test showed the effects of decidual vascular abnormality and acute inflammation on preterm birth to vary with gestational age. At 22 to 28 weeks decidual vascular abnormality and acute inflammation were strongly negatively correlated (p < 0.0001). Of this group there were 23 cases in which both umbilical-chorionic vasculitis and decidual vascular abnormality could be assessed. Three of 16 (19%) with decidual vascular ab-

normality also had umbilical-chorionic vasculitis, whereas 3 of 10 with umbilical-chorionic vasculitis had decidual vascular abnormality (p < 0.0005) and 7 of 23 had umbilical-chorionic vasculitis only (p < 0.0005). At 29 to 32 weeks a significant positive correlation was observed; only 11 of 27 cases with decidual vascular abnormality had umbilical-chorionic vasculitis and 11 of 29 cases with umbilical/chorionic vasculitis had decidual vascular abnormality (p < 0.01). No significant interactions were identified in the other gestational age groups.

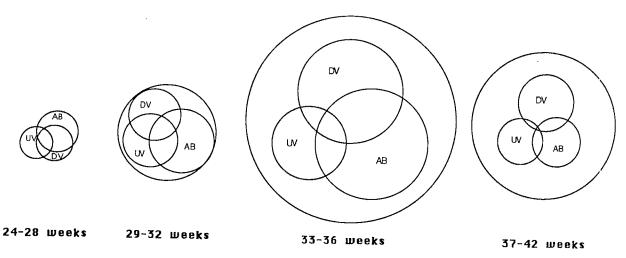

Fig. 2. Association of abruptio placentae (AB), umbilical-chorionic vasculitis (UV), and decidual vascular abnormality (DV).

Table III. Incidence of abruptio placentae and infarct throughout four gestational age groups

	22-28 wk		29-32 wk		33-36 wk		37-42 wk	
	No.	%	No.	%	No.	%	No.	%
Abruptio placentae $(p = 0.0001)$	13/26	50	41/92	45	119/421	28	25/214	12
Infarction $(p = 0.29)$	1/26	4	6/92	7	49/421	12	26/212	12

Given the hypothesis that chronic villositis and decidual vascular abnormality may have related immunopathologic origins, associations between these two processes were examined. At no gestational age was the presence of chronic villitis and decidual vascular abnormality significantly associated.

Abruptio placentae and placental infarcts may result from decidual vascular abnormality. In such instances the decidua may be so damaged as to preclude the actual assessment of the decidual vessels themselves. Of the 67 cases of preterm birth in which decidual vessels could not be assessed, 33 (49%) showed histologic evidence of abruptio placentae. Therefore the incidences of abruptio placentae and infarct were examined (Table III) as additional markers of decidual vascular pathology. Abruptio placentae, as defined in this study, was significantly more frequent in gestations of 22 to 28 weeks (13/26, 50%) as compared with term (25/214, 12%; p < 0.0001). The incidence of placental infarct did not vary significantly throughout gestation, ranging from 4% to 12%.

Clinical abruptio placentae is reported to occur in significantly increased frequency in association with acute inflammation,9 the associations of abruptio placentae as defined histologically, umbilical-chorionic vasculitis, and decidual vascular abnormality also were examined (Fig. 2). No significant interactions between umbilical-chorionic vasculitis, decidual vascular abnormality, and abruptio placentae were noted. Only decreasing gestational age was significantly related to increasing risk of histologic abruptio placentae (p < 0.001). Finally, the correlation between abruptio placentae diagnosed clinically and abruptio placentae defined histologically was examined. Overall, the clinical diagnosis of abruptio placentae was made in 65 to 539 (12%). Abruptio placentae was diagnosed in 7 of 26 (27%) deliveries at 22 to 28 weeks, 18 of 92 (20%) deliveries at 29 to 32 weeks, and 40 of 421 (10%) deliveries at 33 to 36 weeks. Thirty-three of the 65 cases (51%) of clinical abruptio placentae also had histologic evidence. Histologic changes considered to reflect abruptio placentae were diagnosed in 13 of 26 (50%) gestations at 22 to 28 weeks, 41 of 92 (45%) at 29 to 32 weeks, and 115 of 421 (28%) at 33 to 36 weeks. Of the 169 cases of histologic abruptio placentae, the clinical diagnosis of abruptio placentae was made in 33 (19%).

Comment

The data suggest that three separate placental lesions, umbilical-chorionic vasculitis, decidual vascular abnormality, and chronic villitis, are related to preterm birth. All three lesions may represent either acute or chronic inflammatory processes that could causally

be related to preterm birth via various mechanisms. In the case of acute intrauterine infection, generally caused by transcervical ascent of bacteria, the antigenic stimulus initiating the immune cascade of cytokines and prostanoids resulting in labor is exogenous (bacterial) in origin. In decidual vascular abnormality and chronic villitis, an antigenic stimulus may be viral or may arise from the maternal tissues (in autoimmune disorders) or from the fetoplacental unit itself (in alloimmune disorders), inciting chronic inflammation and leading to the respective lesions. The rarity of chronic villitis in early preterm pregnancies may be related to the immaturity of the placental macrophage.10 It is important to recognize that inflammation in the placenta may be represented by different lesions, ranging from simple edema to chronic villitis, depending on the gestational age and degree of functional maturity of the placental macrophage. Chronic maternal-fetal immunologic abnormality at early gestational ages may be reflected only in decidual (implantation site) abnormality. Precocious maturation of immature macrophages may be elicited by cytokines in vitro.11 The observation of chronic villitis at early gestational ages in association with cytomegalovirus infection may indicate a precocious maturation of the placental macrophage in association with maternally or fetally derived cytokines generated in response to the viral stimulus.

Further studies are required to clarify the mechanisms that lead to the placental lesions of decidual vascular abnormality and chronic villitis. Decidual vascular abnormality is recognized to accompany preeclampsia and maternal disease states such as diabetes mellitus, chronic hypertension, and autoimmune disorders, but our data demonstrated frequent decidual vascular abnormality in preterm births of women without evidence of any medical or hypertensive disease. Three placental lesions, umbilical-chorionic vasculitis, decidual vascular abnormality, and chronic villitis, could explain the cause of preterm birth in 96% of births between 22 and 28 weeks, 54% of cases between 29 and 32 weeks, and 46% of cases between 33 and 36 weeks. Current interventions designed to detect and eradicate vaginal pathogens will probably affect less than half of the pregnancies delivered between 24 and 28 weeks' gestation, an age at which risk for short- and long-term morbidity is great. Given the progressive shrinking of medical financial resources, placental examination would appear to be a key factor that may improve targeting of diagnostic and intervention modalities to those who would most benefit. In this study all cases of preterm birth were considered as a group. The further

description of the placental abnormality associated with specific clinical entities, such as preterm labor and premature membrane rupture, is the subject of a separate report.

Finally, in a low-risk community hospital population, abnormalities of the decidual vascular adaptation to pregnancy were identified in 183 of 539 cases (34%) of preterm delivery compared with 115 of 539 cases (21%) of umbilical-chorionic vasculitis. These data may underrepresent the contribution of decidual vascular abnormality to preterm birth, because 33 of the 67 cases (49%) in which decidual vessels could not be assessed had histologic evidence of abruptio placentae. These findings confirm the observations of Fox,12 who observed a 30% correlation of history of abruptio placentae with the presence of a retroplacental hematoma and a 35% correlation of the presence of a retroplacental hematoma with a clinical history of abruptio placentae. In such a low-risk population abnormalities of the placentation process, potentially of an immune etiology, are common correlates of premature birth.

Transfer of aspirin across the perfused human placental cotyledon

Robert L. Jacobson, MD,^a Anthony Brewer, BS,^a Annie Eis, MS,^a Tariq A. Siddiqi, MD,^{a,b,d} and Leslie Myatt, PhD^{a,b,c,d}

Cincinnati, Ohio

Pregnancy-induced hypertension is associated with a reduction in prostacyclin synthesis that is relative to normotensive pregnancy, whereas thromboxane A2 synthesis is unchanged or increased. The net effect is a decreased prostacyclin/thromboxane ratio that may result in the reduced fetal-placental blood flow seen in pregnancy-induced hypertension because thromboxane is known to constrict this circulation, Low-dose aspirin (acetylsalicylic acid), which is used to treat pregnancy-induced hypertension, selectively inhibits thromboxane synthesis and therefore may alter fetal-placental blood flow. We have investigated the transfer of acetylsalicylic acid in the perfused human placental cotyledon and its effects on fetal-placental perfusion pressure. Human placental cotyledons were perfused with tissue culture medium 199 plus 5% polyvinylpyrrolidone that was gassed with 95% oxygen/5% carbon dioxide at flow rates of 10 ml/min (maternal) and 4 ml/min (fetal). Acetylsalicylic acid (10⁻⁵ mol/L) was added to the maternal circuit, and cotyledons were perfused for 1 hour with aliquots taken from a closed fetal circuit every 5 minutes. Acetylsalicylic acid was assayed by spectrofluorometry at 306/412 nm. Our data indicate an initial rapid transfer of ascetylsalicylic acid during the first 5 minutes into the fetal-placental circulation, the concentration then decreased to a steady state at 0.4 × 10⁻⁵ mol/L. Resting perfusion pressure of both maternal and fetal circulation did not change after the addition of acetylsalicylic acid to maternal perfusate and transfer to the fetal circulation. (AM J OBSTET GYNECOL 1991;165:939-44.)

Key words: Low-dose aspirin, placenta, transfer, prostacyclin, preeclampsia

Pregnancy-induced hypertension and preeclampsia are associated with a reduction in uterine blood flow that sometimes leads to intrauterine growth retardation, as well as an increase both in platelet activation and the formation of placental and platelet thromboxane A2,1-5 a potent platelet aggregatory agent6.7 and vasoconstrictor. Although normotensive pregnancy is characterized by an increase in synthesis of vascular prostacyclin,8-10 which is a vasodilator and potent inhibitor of platelet aggregation,11 pregnancy-induced hypertension and preeclampsia are associated with a generalized reduction in prostacyclin synthesis. The reduced prostacyclin/thromboxane ratio of pregnancyinduced hypertension and preeclampsia may therefore result in the hypertension and reduced uterine and fetal-placental blood flow seen in these conditions. Lowdose aspirin (acetylsalicylic acid) may normalize the prostacyclin/thromboxane ratio in pregnancy-induced hypertension and preeclampsia by selectively inhibiting platelet and placental thromboxane and by leaving endothelial prostacyclin production unchanged. Selective inhibition of thromboxane in platelets may inhibit their aggregation in the uteroplacental circulation and may increase blood flow.

Pregnancies complicated by pregnancy-induced hypertension, preeclampsia, and intrauterine growth retardation have a high rate of abnormal systolic/diastolic ratios in the umbilical circulation, which indicates increased fetal-placental vascular resistance and reduced flow. Preliminary studies that used low-dose acetylsalicylic acid (1 to 2 mg/kg/day) suggest a reduction in both the severity and the incidence of pregnancy-induced hypertension^{12, 13} and intrauterine growth retardation, ^{14, 15} as well as an improvement in the systolic/diastolic ratio. In addition, low-dose acetylsalicylic acid has been shown to enhance the pregnancy-acquired refractoriness to angiotensin II in normotensive patients by altering vascular reactivity. ¹⁶

There is a lack of knowledge about the fetal concentration of acetylsalicylic acid that is reached with maternal ingestion of low-dose acetylsalicylic acid and the effects on the fetal-placental circulation. This is of particular interest, because fetal-placental vascular reactivity is, at least in part, mediated by prostaglandins.^{17, 18} The purpose of this in vitro study was

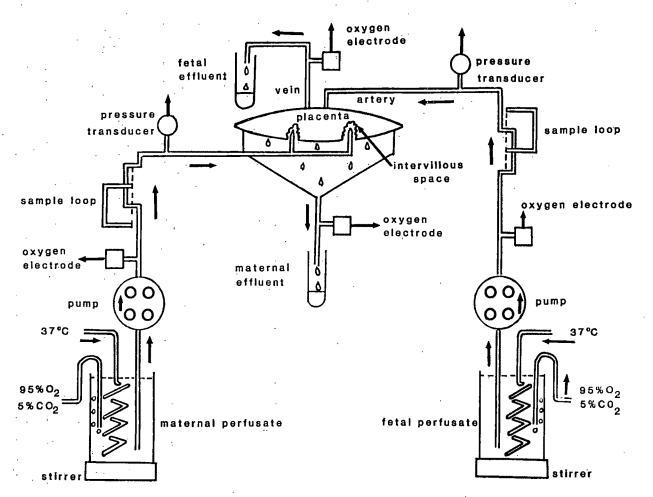

Fig. 1. Dually perfused human placental preparation.

twofold: to determine the transfer kinetics of low-dose acetylsalicylic acid in reaching the fetal circulation of the placenta when acetylsalicylic acid is infused into the intervillous circulation and to determine changes in perfusion pressure in the fetal circulation of the placenta under the influence of low-dose acetylsalicylic acid.

Material and methods

Eleven placentas were collected from normal term vaginal or cesarean section deliveries and were immediately transported to the perfusion laboratory.

The technique of perfusion of the isolated human placental cotyledon is essentially similar to that which we have previously described. Perfusion of the fetal placental circulation was begun at 4 ml/min with tissue culture medium 199 containing 5% polyvinylpyrrolidone 40, 0.1% bovine serum albumin, 48 µg/ml gentamicin, 20 IU/ml heparin; the medium was gassed with 95% oxygen and 5% carbon dioxide at 37° C. Perfusion on the maternal side was then begun at 10 ml/min with the perfusate described. The perfused

cotyledon was placed with the maternal surface downward over a plexiglas cone into which venous effluent from the intervillous space was allowed to drain. Excess nonperfused tissue was then trimmed from around the perfused cotyledon. Examination of the tissue after perfusion was begun revealed uniform blanching. Fetal and maternal effluents were measured to ensure that no perfusion mismatch occurred.

Lateral pressure was measured continuously with three pressure transducers; one was attached to the maternal line and two were attached to the fetal lines. Pressure was recorded on a computerized data acquisition system (IBM PS2, Armonk, N.Y.; Asystant Plus Software, Asyst Technologies, Rochester, N.Y.). Data were captured at a rate of 1 Hz. The entire apparatus including peristaltic pumps was housed in a cabinet maintained at 37° C by a thermostatically controlled electric fan heater (Fig. 1).

All perfusions were established within 20 minutes of placental delivery. Perfusion was continued for 20 minutes to allow the removal of debris, blood, and hypoxic metabolites before experimental manipulation. Oxy-

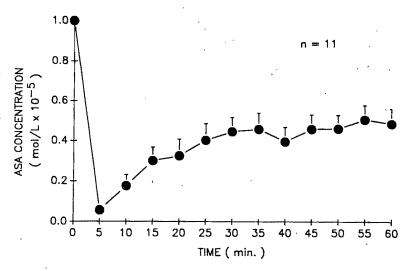

Fig. 2. Extraction of aspirin from maternal perfusate. Acetylsalicylic acid (ASA) (10⁻⁵ mol/L) was added to maternal perfusate and venous effluent was collected at 5-minute intervals and assayed for acetylsalicylic acid (mean \pm SEM; n = 11 experiments).

gen consumption was measured every 5 minutes to ensure placental viability. The pH of the perfusate was measured every 5 minutes and was maintained between 7.36 and 7.40.

After 20 minutes the maternal perfusate was changed to perfusion medium with the addition of acetylsalicylic acid to a final concentration of 10⁻⁵ mol/L, which corresponds to serum levels in women taking low-dose acetylsalicylic acid.20 At the same time the fetal perfusate was changed to a closed circuit containing 150 ml perfusion medium without acetylsalicylic acid. The venous effluent from the maternal side was collected every 5 minutes for 1 hour. Aliquots from the fetal circulation were similarly collected every 5 minutes for I hour. At the end of the experiment the perfused cotyledon was dissected out and weighed. All perfusate samples were centrifuged to remove cellular debris and were stored at -20° C. After all experiments were completed, the samples were thawed for analysis.

A standard curve of acetylsalicylic acid (10⁻⁹ to 10⁻⁵ mol/L) dissolved in perfusion medium that had previously been gassed with 95% oxygen and 5% carbon dioxide at 37° C was constructed (r = 0.964) by measuring the fluorescence on a luminescence spectrometer (LS-5B, Perkin-Elmer, Norwalk, Conn.) at 306/412 nm (excitation emission).21 All samples were then subsequently measured, and the acetylsalicylic acid concentration was computed.

Transplacental parameters were calculated as shown here.

Acetylsalicylic acid clearance (Clasa) was calculated on the basis of the formula:

$$Cl_{\text{ASA}} = \frac{C_{\text{F}} \cdot Q_{\text{F}}}{C_{\text{M}}}$$

where C_F is fetal venous concentration, Q_F is fetal flow

rate (4 ml/min), and C_M is maternal arterial concentration (10⁻⁵ mol/L).

Percent transfer was calculated on the basis of the formula:

Transfer (%) =
$$\frac{C_{\text{F}} \cdot Q_{\text{F}}}{C_{\text{M}} \cdot Q_{\text{M}}} \times 100$$

where Q_M is maternal flow rate (10 ml/min).

Permeability surface area product (P · S) was calculated by means of the formula:

$$P \cdot S = T/\Delta C$$

where T is net flux (moles per minute) and ΔC is maternal-fetal arterial difference.

Normalized permeability surface area product $(P \cdot S_N)$ was calculated according to the formula:

$$P \cdot S_{N} = \frac{P \cdot S}{\text{Wet weight of placenta (gm)}}$$

Multivariate analysis with Wilks' test was used to determine changes in perfusate acetylsalicylic acid concentrations over time.22

Results

There was a rapid extraction of acetylsalicylic acid from the maternal perfusate during the first 5 minutes of perfusion. The extraction rate then decreased and reached steady state by 25 minutes, when approximately 55% of the acetylsalicylic acid was extracted (Fig. 2).

There was a corresponding rapid rise of acetylsalicylic acid concentration in the fetal circulation during the first 5 minutes that reached 0.55×10^{-5} mol/L. The acetylsalicylic acid concentration then decreased slightly and reached steady state by 20 minutes at approximately 0.39×10^{-5} mol/L (Fig. 3). The accu-

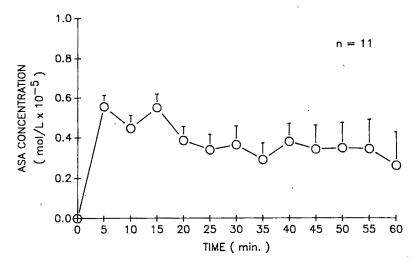

Fig. 3. Aspirin appearance in the tetal circulation. Acetylsalicylic acid (ASA) (10^{-5} mol/L) was added to maternal perfusate, and aliquots were collected every 5 minutes from a closed 150 ml fetal circuit and assayed for acetylsalicylic acid (mean \pm SEM; n=11 experiments).

Table I. Transplacental aspirin transfer parameters n = 11

Acetylsalicyclic acid parameters	$Mean \pm SE$		
Clearance, 5 min (ml/min)	2.22 ± 0.24		
Transfer 5 min (%)	22.19 ± 2.38		
Clearance, steady-state (ml/min)	1.54 ± 0.28		
Transfer, steady-state (%)	15.41 ± 2.75		
Permeability surface area produce (ml/min)	17.00 ± 1.78		
Normalized permeability surface area produce (ml/min/gm)	0.65 ± 1.31		

mulation of acetylsalicylic acid in the fetal circulation paralleled that of the apparent "maternal" extraction.

Acetylsalicylic acid clearance from maternal to fetal circulation was calculated to be 2.22 ml/min during the first 5 minutes; there was a 22% transfer of acetylsalicylic acid to the fetal circulation. Permeability surface area produce was 17 ml/min, and normalized permeability surface area produce was 0.647 ml/gm/min. At steady state acetylsalicylic acid clearance was 1.54 ml/min and the transfer from the maternal to fetal circulation was 15% (Table I).

There was obvious uptake of acetylsalicylic acid by the placental tissue. At steady state approximately 75% of the acetylsalicylic acid extracted from the maternal circulation (5.96 \times 10^{-8} mol/min) was taken up by placental tissue. When the placenta was perfused with 10^{-5} mol/L acetylsalicylic acid on the maternal side, concentrations in the fetal circulation did not exceed 0.55×10^{-5} mol/L.

There was no change in fetal perfusion pressure after the maternal circulation was perfused with 10^{-5} mol/L acetylsalicylic acid (Fig. 4).

Comment

Acetylsalicylic acid, as a result of its low molecular weight (180.2 gm), was able to cross the placenta rapidly; this is indicated by its rapid appearance in the fetal circulation during the first 5 minutes. The mean concentration of acetylsalicylic acid in the fetal circulation significantly increased over the first 5 minutes to reach a concentration of 0.55 \pm 0.06 \times 10⁻⁵ mol/L (mean \pm SEM), which was followed by a slight decrease with steady state reached by 20 minutes at a concentration of $0.39 \pm 0.07 \times 10^{-5}$ mol/L (mean \pm SEM). Multivariate analysis with Wilks' test showed significant overall change in acetylsalicylic acid concentration with time (p = 0.024). There was a significant increase in acetylsalicylic acid concentrations in the fetal circulation between 0 and 5 minutes. There was then a slight but significant reduction in acetylsalicylic acid concentration between 5 and 20 minutes (p < 0.0225) but there was no additional significant change after steady state

Multivariate analysis with Wilks' test again showed significant alterations in maternal acetylsalicylic acid concentrations with time (p = 0.047). There was a rapid significant extraction of acetylsalicylic acid from the maternal perfusate during the first 5 minutes of perfusion. The extraction rate then decreased and concentrations in the maternal venous effluent significantly increased by 25 minutes (p = 0.0012) with no additional significant change at steady state. At steady state approximately 60% of the acetylsalicylic acid was extracted, which left a concentration of $0.40 \pm 0.08 \times$ 10⁻⁵ mol/L in the maternal venous effluent. Rapid extraction of acetylsalicylic acid during the first 5 minutes was probably a result of the high concentration gradient between the two circulations; this resulted in the transfer of acetylsalicylic acid across the placenta. After 5

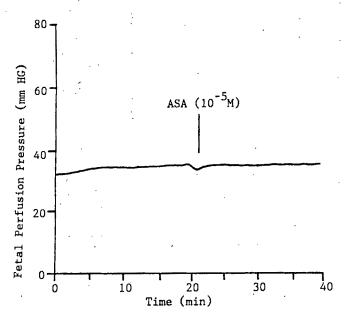

Fig. 4. Effect of addition of 10⁻⁵ mol/L acetylsalicylic acid (ASA) into maternal circulation of perfused placenta on fetal perfusion pressure. Data from typical experiment are shown.

minutes the concentration gradient was smaller and steady state was reached. The extraction of acetylsalicylic acid from the maternal perfusate parallels the appearance of acetylsalicylic acid in the fetal circulation.

At steady state the constant concentrations in both circulations suggest that the uptake of acetylsalicylic acid from the maternal circulation equals the metabolism of acetylsalicylic acid by the placenta. The loss of acetylsalicylic acid from the maternal circulation exceeded the accumulation of ascetylsalicylic acid in the fetal circulation by 75%, which presumably was a result of uptake and/or metabolism by the placenta. The results obtained for clearance, transfer, and permeability surface area product and its normalized derivative are consistent with other reports for substances with similar molecular weights and physical properties.23,24 Acetylsalicylic acid transfer (22% at 5 minutes and 15% at steady state) resulted in concentrations in the fetal circulation $(0.39 \times 10^{-5} \text{ mol/L})$ that were lower than those known to inhibit thromboxane and that have been shown not to affect prostacyclin synthesis in chorionic plate vessels in vitro.20 It is unlikely that low-dose acetylsalicylic acid given to pregnant women would alter fetal prostacyclin synthesis.25 In addition, the metabolism of acetylsalicylic acid in both fetal and maternal compartments is likely to lower the acetylsalicylic acid concentration further in the fetal circulation.

There was no change in fetal perfusion pressure after the maternal circulation was perfused with 10⁻⁵ mol/L acetylsalicylic acid. Although prostaglandins and thromboxane have been shown to mediate vascular reactivity in the perfused placenta, the effects are only manifest when tone'is induced in the system.18 If the fetal-placental circulation is maximally dilated at resting perfusion pressure, then alteration in prostaglandin synthesis might not produce an observable effect. The lack of change in fetal perfusion pressure during maternal infusion of acetylsalicylic acid supports this contention, which is in agreement with our previous observation¹⁷ that the cyclooxygenase inhibitor indomethacin did not affect resting perfusion pressure. However, if prostacyclin synthesis is important in regulating resting vascular tone, then we are observing a lack of inhibition of prostacyclin with this concentration of acetylsalicylic acid. Measurement of prostacyclin and thromboxane in the fetal-placental circulation during perfusion with acetylsalicylic acid will resolve this.

We thank Diane Dotson, Beth Bourne, Diane Brockman, Gretchen Langdon, and Jane Khoury for their assistance in the preparation of this manuscript.

Report of fourteen cases of nonimmune hydrops fetalis in association with hemorrhagic endovasculitis of the placenta

Patricia M. Novak, DO,^a C. Maureen Sander, MD,^b S. Samuel Yang, MD,^a and Paul T. von Oeyen, MD^c

Royal Oak, East Lansing, and Detroit, Michigan

Hemorrhagic endovasculitis of the placenta is a distinct vasodestructive process of unknown cause that has been associated with perinatal morbidity and mortality. A relationship between nonimmune hydrops fetalis and hemorrhagic endovasculitis has not been previously described. At a large teaching hospital, six cases of nonimmune hydrops fetalis were identified out of 72 cases of hemorrhagic endovasculitis over 6 years, for an incidence of 8%. Conversely, these same six cases represented 24% of the 25 cases of nonimmune hydrops fetalis from this time period. Eight additional cases of nonimmune hydrops fetalis were found among 2064 cases of hemorrhagic endovasculitis at the Michigan Placental Tissue Registry. In eight of the total 14 cases, after congenital malformations and cytomegalovirus infections were excluded, hemorrhagic endovasculitis was the only significant associated pathologic finding evident. The significance of the relationship between nonimmune hydrops fetalis and the vascular abnormalities of hemorrhagic endovasculitis remains to be determined. (AM J OBSTET GYNECOL 1991;165:945-50.)

Key words: Nonimmune hydrops fetalis, hemorrhagic endovasculitis, placental pathology, perinatal outcome

Hemorrhagic endovasculitis of the placenta is a distinct vasodestructive process of unknown cause first described in 1980.1 Its major histopathologic features include variable occlusion of chorionic vessels of all sizes by myointimal proliferation and mural and luminal thrombi in which fragmented erythrocytes and occasional nucleated red cells are entrapped. Mural nonexudative necrosis with hemorrhage into the surrounding villous stroma is also prominent, and a proliferative villous stromal response, referred to as hemorrhagic villitis, also may occur.2 A significant association between hemorrhagic endovasculitis and stillbirth, intrauterine growth retardation, and developmental abnormalities in surviving infants, including mental retardation, cerebral palsy, optic atrophy, hearing loss, and learning disabilities, has been reported.^{3,4} Nonimmune hydrops fetalis has been associated with various conditions; however, approximately 20% remain idiopathic.5,6 A relationship between the two disorders has not been previously described. A case of coexistence prompted our investigation into a possible association between these two entities.

Material and methods

Medical records from January 1985 through December 1990 at William Beaumont Hospital, a large teaching hospital, were reviewed for both live births and stillbirths of infants with nonimmune hydrops fetalis in cases in which the placentas had been examined. All relevant placental histologic slides, routinely stained with hematoxylin and eosin, were then assessed for the presence of hemorrhagic endovasculitis by two independent examiners. The files of the anatomic pathology department were searched for all cases of hemorrhagic endovasculitis diagnosed among the total number of placentas examined during this same time period. These were subsequently reviewed for clinical evidence of nonimmune hydrops fetalis. The χ^2 test was used to test for an association between these two qualitative variables from the data acquired at this institution. Additionally, the files of the Michigan Placental Tissue Registry, a statewide referral center, were searched for cases of nonimmune hydrops fetalis among cases of hemorrhagic endovasculitis between 1982 and the first half of 1990.

Results

At William Beaumont Hospital, 3419 placentas from 33,838 deliveries were submitted for histologic examination during the 6 years spanning January 1985 through December 1990. Of these, 72 had microscopic features diagnostic of hemorrhagic endovasculitis. Six cases of nonimmune hydrops fetalis were identified out of these 72, for an incidence of 8%. Conversely, these same six cases of hemorrhagic endovasculitis representations.

sented 24% of the total 25 cases of nonimmune hydrops fetalis at this institution from this time period. With strict criteria, there was 100% interobserver agreement regarding the presence of hemorrhagic endovasculitis in the reviewed placental histologic slides. Additionally, with one exception, all were correctly diagnosed by the original reporting pathologists. The statistical processing of the results by χ^2 test shown in Table I provides support for a significant association between the finding of hemorrhagic endovasculitis with nonimmune hy-

drops fetalis (p < 0.001); however, this does not necessarily imply causality. The odds ratio, as an approximation of relative risk for nonimmune hydrops fetalis in the presence of hemorrhagic endovasculitis, is 15.9. An additional eight cases of nonimmune hydrops fetalis were found among the 2064 cases of hemorrhagic endovasculitis from a total of 12,916 placentas examined at the Michigan Placental Tissue Registry during the $8\frac{1}{2}$ years being considered. Clinical and pathologic findings in the 14 cases of nonimmune hydrops fetalis

in association with hemorrhagic endovasculitis from both institutions are summarized in Table II. Of the total, there were eight stillbirths and four neonatal deaths. One infant survives, and one is lost to followup. The two examples which follow are representative of some of the clinical and pathologic features of these cases.

Case reports

Case 4. A female infant was delivered at 36 weeks' gestation by cesarean section of a 31-year-old mother with gestational diabetes mellitus. An ultrasonographic examination performed at 32 weeks had revealed marked polyhydramnios, severe fetal hydrops, large pleural effusions, ascites, and a questionable pericardial effusion (Fig. 1). Isoimmunization was ruled out, the Kleihauer-Betke test was negative, there was no hemoglobinopathy, serologic findings for relevant infectious agents were not significant, and chromosomal analysis showed a 46,XX karyotype. At birth, the generally edematous 2700 gm infant was limp, apneic, and bradycardiac. She was successfully ventilated after bilateral thoracentesis. In spite of aggressive mechanical ventilation, she died at 36 hours of age of apparent respiratory failure. Postmortem examination disclosed bilateral severe pulmonary hypoplasia, hyaline membrane disease, interstitial emphysema, and a right pneumothorax, in addition to pleural and peritoneal effusions. The placenta showed severe hemorrhagic endovasculitis exclusively (Figs. 2 and 3).

Case 5. A female infant was delivered at 37 weeks' gestation by cesarean section of a 32-year-old mother. After a report of decreased fetal activity, an ultrasonographic examination at 35 weeks had revealed polyhydramnios, massive pleural effusions, ascites, and skin edema. Isoimmunization was ruled out, the Kleihauer-

Betke test was negative, no hemoglobinopathy was demonstrated, serologic findings and microbiologic cultures for relevant infectious agents were negative, and chromosomal analysis was reported as 46,XX. At birth the 3799 gm edematous infant showed decreased tone and respiratory distress that required endotracheal intubation and mechanical ventilation. Worsening bilateral pleural effusions improved after thoracentesis on the seventh day after birth. Echocardiogram at 8 days showed decreased ventricular contractility with an ejection fraction of 62%, and she required medical therapy for hypertension. The hydrops gradually improved, and she was extubated and subsequently discharged at 1 month of age in stable condition on a regimen of digoxin. At 5 months, the infant was no longer taking cardiac medication, and a repeat echocardiogram was normal. Placental examination had disclosed focal hemorrhagic endovasculitis and villous edema (Figs. 4 and 5).

Comment

The development of nonimmune hydrops fetalis previously has been related to a number of fetal, placental, and maternal disorders. The more common causative factors cited include fetal heart disease, other intrathoracic abnormalities, nonimmune anemia, fetal infection, and fetal circulatory obstruction.5,6 In eight of the 14 cases presented here, after exclusion of congenital malformations (including trisomy 21, Turner syndrome, Turner phenotype with cystic hygroma, and cystic adenomatoid malformation of the lung) and cytomegalovirus infections, hemorrhagic endovasculitis was the only significant pathologic finding evident. As the characteristic alteration in hemorrhagic endovasculitis involves the destruction of fetal placental blood

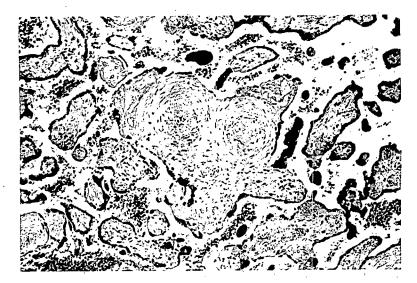

Fig. 2. Placenta with hemorrhagic endovasculitis from case 4. Near-total occlusion of three chorionic vessels of large central villus caused by proliferation of spindle cells. Note entrapped and fragmented red blood cells. Villus in lower right-hand corner exhibits features of hemorrhagic villitis. (Hematoxylin and eosin. Original magnification $\times 120$.)

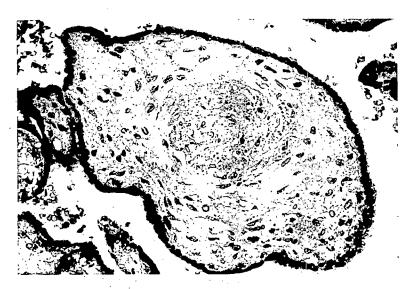

Fig. 3. Placental villus from case 4. Centrally located hemorrhagic endovasculitis—affected vessel with red blood cell fragments within its lumen and wall. (Hematoxylin and eosin. Original magnification ×300.)

vessels, red blood cell damage, enhanced coagulation, and intravillous hemorrhage, whether fetal blood loss by fetal-placental hemorrhage can be implicated in the development of hydrops fetalis in this setting is an interesting possibility that deserves further consideration. Alternatively, perhaps hypoxia may effect the fetal vascular damage that occurs in hemorrhagic endovasculitis, in which case placental ischemia as a possible etiologic factor in nonimmune hydrops fetalis deserves attention. Finally, there is always a possibility that both hemorrhagic endovasculitis and nonimmune hydrops

fetalis may be caused by a common, as yet undisclosed etiologic factor.

Statistical analysis was applied only to the results obtained from that part of the study conducted at William Beaumont Hospital and as such supports a significant relationship between hemorrhagic endovasculitis and nonimmune hydrops fetalis. Similar statistical testing was not possible with the data available from the Michigan Placental Tissue Registry; however, results from inquiry into its files were nonetheless enlightening. The disparate incidence of nonimmune hydrops fetalis in

Fig. 4. Placental villus with hemorrhagic endovasculitis from case 5. Chorionic vessels with narrowed lumina. Note diapedesis of red blood cells, some of which are fragmented, through wall of larger vessel. (Hematoxylin and eosin. Original magnification ×300.)

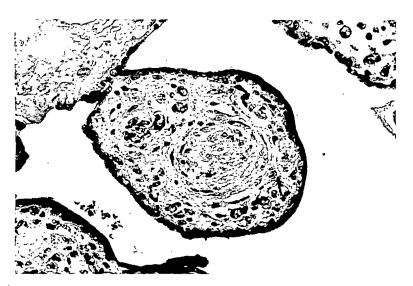

Fig. 5. Placental villus with hemorrhagic endovasculitis from case 5. Medium-sized vessel showing total occlusion by myointimal proliferation. Note entrapped red blood cells. (Hematoxylin and eosin. Original magnification ×300.)

association with hemorrhagic endovasculitis found at the two institutions involved may be explained by the highly selective nature of the cases submitted to the Michigan Placental Tissue Registry. Placentas are usually sent to this consultation center because of some characteristic of pregnancy or its outcome that is of special interest to the referring physician. Also, complete and relevant clinical information may not be as readily available in this situation.

This study supports the previously reported prognostic observation that there is an apparent doseresponse relationship between the severity of placental

involvement with hemorrhagic endovasculitis and pregnancy outcome.4 In the only two cases in which the infant survived beyond the neonatal period, focal, rather than diffuse, hemorrhagic endovasculitis was found. In the only other case where the placenta showed only focal involvement, the fetus was stillborn but also had multiple serious anomalies. The incidence of hemorrhagic endovasculitis varies from 0.67% of unselected pregnancies,8 to 2.1% among placentas submitted for examination at William Beaumont Hospital, to 19.4% at the Michigan Placental Tissue Registry. The incidence of hemorrhagic endovasculitis in unselected pregnancies might be higher than the reported 0.67%, for in the cited prospective study only two microscopic sections from each placenta were examined rather than more extensive sampling being done.

Finally, an appropriate investigation into the possible cause of nonimmune hydrops fetalis in a specific case is important not only for the immediate treatment of the neonate but also for the management of subsequent pregnancies. It has been reported that hemorrhagic endovasculitis, like nonimmune hydrops fetalis, carries a risk for recurrence.³ Future attention to the association of nonimmune hydrops fetalis and hemorrhagic endovasculitis hopefully will contribute to better understanding of the interrelationship between these entities

Nifedipine pharmacokinetics and pharmacodynamics during the immediate postpartum period in patients with preeclampsia

John R. Barton, MD, Rebecca R. Prevost, PharmD, Donald A. Wilson, MD, W. David Whybrew, MS, and Baha M. Sibai, MD

Memphis, Tennessee

Pharmacokinetic and pharmacodynamic parameters of oral nifedipine were studied in the immediate postpartum period in eight women with preeclampsia. Peak serum concentrations of $18 \pm 2.1~\mu g/L$ occurred 40 minutes after ingestion of nifedipine (10 mg). The terminal elimination half-life (mean = 1.35 ± 0.3 hours) was found to be shorter than that reported for normotensive volunteers or nonpregnant hypertensive women (mean, 3.4 ± 0.4 hours). A mean apparent oral elimination clearance of $3.3 \pm 1.3~L/hr/kg$ was more rapid than that found in normal volunteers (mean, $0.49 \pm 0.09~L/hr/kg$) or in women with pregnancy-induced hypertension in the third trimester (mean, $2.0 \pm 0.8~L/hr/kg$). Initial nadirs in mean arterial pressure were noted at 50 minutes after ingestion of nifedipine, with an average reduction in mean arterial pressure of 13.8~mm Hg. A dosing interval of every 3 to 4 hours is suggested when rapid-release nifedipine is used in the postpartum patient with preeclampsia. (AM J OBSTET GYNECOL 1991;165:951-4.)

Key words: Nifedipine, pharmacokinetics, preeclampsia

Approximately 7% of all pregnancies are complicated by hypertension with preeclampsia; this is responsible for 70% of all hypertension occurring in pregnancy. The diagnosis of preeclampsia is based on the presence of hypertension and proteinuria or edema or both. In most patients the hypertension associated with preeclampsia appears to be a secondary effect of generalized vasospasm. Because of this associated vasospasm, antihypertensive agents with vasodilatory properties are very desirable. The current standard treatment for severe hypertension associated with preeclampsia is the intravenous administration of hydralazine.⁵

During the past several years many new antihypertensive agents have become available. One such agent, the calcium channel antagonist nifedipine, has potent activity against vascular and extravascular smooth muscle contractions. Dosage is usually initiated at 10 mg given orally three times a day. It has also been shown to promptly and effectively resolve elevated blood pressure in antepartum patients with pregnancy-induced hypertension, as well as severe preeclampsia in the postpartum period, but data are limited. The pharmacokinetics of nifedipine have been evaluated in non-

pregnant subjects, ¹⁰ in women during preterm labor tocolysis, ¹¹ and in women in the third trimester with pregnancy-induced hypertension. ¹² This investigation was designed to determine the pharmacokinetic disposition and pharmacodynamics of oral nifedipine during the immediate postpartum period in patients with preeclampsia.

Material and methods

Eight women with an intrapartum diagnosis of preeclampsia were invited to participate in the study, following guidelines established by the institutional review board at the University of Tennessee, Memphis. Preeclampsia was diagnosed on the basis of the criteria established by the Committee on Terminology of the American College of Obstetricians and Gynecologists.13 Patients were excluded from participation if their medical history revealed an adverse reaction to calcium channel blockers, if they had used a calcium channelblocking agent within 8 hours before the investigation, or if they required supplemental therapy with other antihypertensive agents during the course of the postpartum pharmacokinetic evaluation. All patients received standard therapy for preeclampsia in the postpartum state, including bed rest and a continuous infusion of magnesium sulfate at a dose required to maintain a serum concentration between 6 and 8 mg/dl. The primary intravenous fluid was 5% dextrose in lactated Ringer's solution, and total intravenous fluid intake was maintained at 100 ml/hr. Oral intake was not permitted during the study. After patients gave antepartum informed consent to participate in the pharmacokinetic evaluation, arterial catheters were

placed in either the right or left radial artery for blood pressure monitoring and phlebotomy access. Once delivered and in the recovery room, the patients were placed in a supine position with the heads of the beds elevated to approximately 30 degrees. The arterial catheter was positioned and flushed, and an automated blood pressure monitor was placed on the patient's opposite arm. Blood pressure was measured at baseline and every 10 minutes for the first hour, then at 70, 80, 120, 180, 240, and 360 minutes after the study dose of nifedipine. A 5 ml blood sample was obtained immediately before oral intake of the study dose of 10 mg nifedipine. Postdose blood samples were obtained at 20, 40, 60, 80, 120, 180, 240, and 360 minutes. The samples were collected in subdued lighting, protected from light during transport, and centrifuged immediately after collection. The serum was stored at -70° C until analysis. Samples were analyzed by highperformance liquid chromatography. A Hewlett Packard 1084 chromatograph (Hewlett Packard, Avondale, Pa.) equipped with a variable wavelength detector was used for analysis. Separation was achieved with an LC-8DB, 15 cm \times 4.6 mm, 5 μ m column (Supelco, Inc., Bellefonte, Pa.). Acetonitrile and potassium phosphate buffer, 50 mm (55:45), was the mobile phase of choice. Peak detection was achieved at 236 nm, 0.008 AUFS (absorbance units full scale). Flow rate was 1 ml/min. Serum nifedipine concentrations were measured after extraction of nifedipine and chlorpropamide (internal standard) on Supelclean LC-8 SPE tubes (Supelco). One milliliter of serum was diluted to 5 ml with milli Q water (Millipore Inc., Bedford, Mass.), applied to preactivated cartridges, and eluted with 500 µl of tetrahydrofuran. The resulting eluant was dried in the dark under a stream of nitrogen gas. The residue was resuspended in 200 µl of mobile phase, and 20 µl was assayed for nifedipine concentration. The assay's lower limit of sensitivity was <5 ng/ml. Samples were run in duplicate.

The serum concentration versus time data from the β (terminal) elimination phase was fitted to a single exponential term (ke, the elimination rate constant) by use of a multilinear least-squares regression program. The terminal elimination half-life (t 1/2) was calculated from the equation:

$$t 1/2 = 0.693/ke$$

Noncompartmental analysis was used to estimate clearance and area under the serum concentration versus time curve, because this method does not assume the elimination data fit a chosen model. ¹⁴ The area under the serum concentration versus time curve was calculated by the trapezoidal rule. Apparent oral elimination clearance was expressed in relation to actual body weight and was calculated from the equation:

$$\frac{\text{Clo} = \text{dose per kg body weight}}{\text{AUC}_{0.6}}$$

where Clo is apparent oral clearance and $AUC_{0.6}$ is area under the concentration versus time curve from 0 to 6 hours.

Results

The eight patients all had preeclampsia and were in the immediate postpartum period. All patients had proteinuria, but none had evidence of chronic renal disease. In one patient the syndrome of hemolysis, elevated liver functions, and low platelets (HELLP syndrome) developed. Five of the eight patients received intravenous hydralazine in the antepartum period for systolic blood pressure >160 mm Hg or diastolic blood pressure >110 mm Hg. Nifedipine was well tolerated

Mean ± SD	80.8 ± 20.4	132.5 ± 41.4		1.35 ± 0.3	3.3 ± 1.3	40.8 ± 6.2	18.3 ± 1.9

Pharmacokinetic data, group means, and standard deviations after oral administration of 10 mg nifedipine. Ke, Elimination rate constant; t½, elimination half-life; Clo, apparent oral elimination clearance; Auc, area under the concentration versus time curve; Cmax, maximum serum concentration.

by all patients, with headache being the only adverse effect reported. Nifedipine was undetectable in eight of eight patients at time 0 and in six of eight patients at 360 minutes. Peak serum concentration occurred at 40 minutes, which was the timing of the second sample collection.

The mean serum concentration versus time graph is depicted in Fig. 1. All patients entered the terminal elimination phase at approximately 40 minutes after drug ingestion. Whereas patient concentrations were variable, the declining concentrations were fitted to a one-compartment model well, with a correlation coefficient (mean \pm SD) of 0.984 \pm 0.01. The pharmacokinetic parameters for each patient are described in Table I. The serum half-life (mean \pm SD) was 1.35 \pm 0.3 hours, with a range of 0.96 to 1.74 hours. Oral clearance (mean \pm SD) was 3.3 \pm 1.3 L/kg/hr, with a range of 2.1 to 5.8 L/kg/hr.

The initial mean arterial blood pressure averaged 107.5 mm Hg when taken by the automatic blood pressure cuff and 109.0 mm Hg when recorded from the arterial line, with an average during therapy of 100.7 and 101.1 mm Hg, respectively. Initial nadirs were noted at 50 minutes with an average of 93.7 and 98.3 mm Hg, respectively, correlating well with the timing of the peak serum concentration at 40 minutes (Fig. 2).

Comment

Nifedipine, a dihydropyridine derivative, is a calcium channel blocker with potent peripheral arterial vasodilating properties. The drug has been used in the successful treatment of hypertension since 1976. Extensive reviews leave indicate that single-dose nifedipine is associated with a 25% reduction in systolic blood pressure, diastolic blood pressure, and mean arterial pressure in 98% of cases. Walters and Redman⁶ reported excellent resolution of hypertension, without any adverse maternal or fetal effects, when treating pregnant women with severe preeclampsia. Barton et al. re-

ported a reduction in mean arterial blood pressure when treating hypertension associated with severe preeclampsia in the postpartum period. Furthermore, nifedipine has also been reported to improve renal function with a beneficial effect on urine output when treating preeclampsia in the postpartum period.⁹

Many pathophysiologic changes occur during pregnancy, preeclampsia, and in the postpartum period, which may affect drug disposition and ultimately be responsible for altered pharmacologic activity. In our patients a mean peak nifedipine serum concentration of $18 \pm 2.1 \,\mu g/L$ was achieved 40 minutes after a 10 mg oral dose. Previous studies of nifedipine after a 10 mg oral dose found peak serum concentration to be $38.6 \pm 1.8 \,\mu g/L$ at 40 minutes in women with pregnancy-induced hypertension in the third trimester¹² and $73.48 \pm 17.48 \,\mu g/L$ in nonpregnant normal subjects. 10 The difference may be due to enhanced firstpass elimination in our pregnant and postpartum population. Nifedipine is eliminated metabolically during the first pass through the liver and therefore only an estimated 60% to 70% of the dose enters the systemic circulation in nonpregnant patients.21 Furthermore, nifedipine has been shown to increase hepatic blood flow as a result of arterial vasodilatation.22 Another factor most likely to contribute to our patients' lower peak serum concentrations is the increased intravascular volume that results from fluid shifts during the postpartum period in patients with preeclampsia. The mobilization of fluid from the extravascular to the intravascular space increases the serum volume of distribution, therefore decreasing the highest serum concentration achieved.

Serum concentrations were undetectable in most patients at 360 minutes. This once again confirms lack of drug accumulation previously reported in pregnant patients with dosing every 6 hours^{11, 12} and raises concern over the adequacy of a 6- to 8-hour dosing interval.

The terminal elimination half-life was found to be 1.35 ± 0.3 hours, which confirms the findings of Fer-

guson et al., ¹¹ who found a half-life of 1.3 ± 0.43 hours in third-trimester women receiving nifedipine for to-colysis and Rogers et al., ¹² who found a half-life of 1.3 ± 0.5 hours in third-trimester patients with pregnancy-induced hypertension. This half-life is shorter than that reported in nonpregnant controls. ¹⁰ The shortened half-life appears to be due to the physiologic changes of pregnancy and not to factors exclusively associated with preeclampsia, the postpartum period, pregnancy-induced hypertension, or preterm labor.

The clearance of nifedipine was greater in our population (3.3 \pm 1.3 L/hr/kg) than in third-trimester women receiving nifedipine for pregnancy-induced hypertension (2.0 \pm 0.8 L/hr/kg). and in nonpregnant controls (0.49 \pm 0.09 L/hr/kg). The increased clearance of nifedipine in our patients appears to be due to the increased intravascular volume resulting from fluid shifts occurring during the postpartum period in patients with preeclampsia.

In summary, this study confirmed a shorter half-life and found a more rapid clearance and lower peak serum concentration for nifedipine in patients during the postpartum period with preeclampsia than in nonpregnant controls. Moreover, our results found a more rapid clearance and lower peak serum concentration for nifedipine in postpartum patients with preeclampsia when compared with third trimester women receiving nifedipine for pregnancy-induced hypertension. Finally, our results suggest that nifedipine may be efficacious in treating hypertension associated with preeclampsia in the postpartum period; however, because of the pharmacokinetic changes described, dosage, and dosing intervals (i.e., every 3 to 4 hours) may need to be altered. The rapid-release capsule is of vital importance when titrating the dose to the patient's individual response. Thereafter, the sustained release form of nifedipine may be more practical and may improve compliance.

Microbiologic causes and neonatal outcomes associated with chorioamnion infection

Sharon L. Hillier, PhD, Marijane A. Krohn, PhD, Nancy B. Kiviat, MD, D. Heather Watts, MD, and David A. Eschenbach, MD Seattle, Washington

Chorioamnion infection is associated with histologic chorioamnionitis and prematurity, but the specific chorioamnion microorganisms associated with histologic chorioamnionitis, prematurity, and poor neonatal outcome have not been identified. Bacteria were recovered from the chorioamnion cultures of 32% of 112 placentas delivered at ≤34 weeks' gestation and from 19% of 156 placentas delivered at >34 weeks' gestation (odds ratio 2.1; 95% confidence interval 1.1 to 3.8). Chorioamnion bacteria most highly related to both prematurity and histologic chorioamnionitis were group B Streptococcus and Fusobacterium species. Chorioamnion infection with Peptostreptococcus was significantly related only to preterm delivery, and infection with Escherichia coli, Bacteroides, and Ureaplasma were significantly related to histologic chorioamnionitis. Among preterm infants, isolation of bacteria from the chorioamnion was related to an increased risk of neonatal death (rate ratio 3.8; 95% confidence interval 1.4 to 11.6). Bacterial infection of the chorioamnion is related to preterm birth, histologic chorioamnionitis, and neonatal death. (AM J OBSTET GYNECOL 1991;165:955-61.)

Key words: Chorioamnion infection, chorioamnionitis, neonatal mortality

Recent studies have shown a positive relationship between preterm delivery, chorioamnion infection, and histologic chorioamnionitis. Microorganisms are recovered 2 to 4 times more frequently from the chorioamnion of placentas delivered before term than those delivered at term.1-3 Histologic chorioamnionitis is detected in 19% to 74% of placentas delivered preterm compared with 4% to 16% of placentas delivered at term. 1, 4-6 Chorioamnion infection and histologic chorioamnionitis are closely related but not synchronous. Microorganisms have been recovered from 51% to 71% of placentas with histologic chorioamnionitis, compared with 23% to 45% of those without histologic chorioamnionitis.1,2,7,8 Prolonged labor or rupture of membranes may result in colonization of the upper genital tract by vaginal bacteria. However, chorioamnion infection was associated with preterm delivery in one study after these potential confounding factors were controlled by logistic regression.1

The microorganisms most commonly recovered from the chorioamnion include *Ureaplasma urealyticum*,

From the Departments of Obstetrics and Gynecology, Epidemiology, and Pathology, University of Washington.

Supported by grant HD-AI22192 from the National Institutes of Health.

Presented at the Eleventh Annual Meeting of the Society of Perinatal Obstetricians, San Francisco, California, January 28—February 2, 1991.

6/6/31178

facultative and anaerobic gram-positive cocci, Gardnerella vaginalis, and Bacteroides species. 1. 2. 6-8 Haemophilus influenzae, Neisseria gonorrhoeae, and Chlamydia trachomatis are rarely recovered from the placenta. 1. 8-10 The recovery of microorganisms from term placentas and from placentas without inflammation raises the possibility that only certain microorganisms are associated with preterm delivery and histologic chorioamnionitis. Too few subjects have been included in any one study to identify the particular microorganisms associated with preterm birth. Except for *U. urealyticum*, no specific microorganisms have been associated with histologic chorioamnionitis. 8

Amniotic fluid infection has been associated with neonatal respiratory distress syndrome and neonatal infectious morbidity.¹¹ Histologic chorioamnionitis has been associated with perinatal death, elevated antibody levels to *U. urealyticum*,⁸ and sepsis within 48 hours of birth.⁵ Neonatal outcome in pregnancies with chorioamnion infection has not been reported.

One purpose of this study was to confirm the relationship between chorioamnion infection and preterm delivery and histologic chorioamnionitis after accounting for potentially confounding labor variables. The second purpose of this study was to determine whether individual microorganisms infecting the chorioamnion were associated with preterm delivery and histologic chorioamnionitis. The third purpose was to determine whether chorioamnion infection was associated with neonatal death or respiratory distress syndrome.

Material and methods

Women were enrolled between October 1987 and March 1990 from the labor and delivery unit of University of Washington Medical Center. Women who agreed to participate in the study signed consent forms approved by the University of Washington Human Subjects Review Committee. All women admitted to the labor and delivery unit during weekdays were screened for eligibility. Women were excluded from enrollment if they were <16 years or >40 years of age, had documented uterine or fetal anomalies, hypertension, diabetes, placenta previa, abruptio placentae, cervical cerclage, or fetal distress, or had received antibiotics in the previous week. The number of women in preterm labor who were screened and excluded or approached for the study has been previously published.12 After a subject was enrolled, the next eligible control woman who was delivered within daytime working hours was enrolled.

The case group consisted of 146 women admitted to the hospital in preterm labor at a gestational age of 22 to 34 weeks and who were delivered at ≤34 weeks' gestation. We defined prematurity as a gestational age of ≤34 completed weeks because the prevalence of chorioamnion infection and histologic chorioamnionitis is stable at >35 weeks' gestation.1.5 Preterm labor was defined as regular painful contractions occurring at least every 10 minutes accompanied by progessive cervical dilatation or by a Bishop score >4 that included ≥50% cervical effacement and ≥1 cm dilatation. 18 Preterm premature rupture of membranes was defined as spontaneous rupture of membranes before the onset of contractions at a gestational age of 22 to 34 weeks. The control group consisted of 184 women without preterm labor who were delivered at >34 weeks' gestation and 74 women who were enrolled in preterm labor but were delivered at >34 weeks' gestation. Chorioamnion cultures and histologic samples were obtained from 112 (77%) of the women in the group of 146 cases, 35 (47%) of the 74 women enrolled in labor at ≤34 weeks' gestation who were delivered at >34 weeks, and 121 (66%) of the 184 controls. Only patients with both chorioamnion culture and placental histologic results were included in this report. The data for the two groups of women delivering at ≥34 weeks' gestation were similar with respect to chorioamnion infection and histologic chorioamnionitis, so the data were combined for a total of 156 control women. The median gestational age was 31 weeks for the case group and 39 weeks for the control group. Gestational age was estimated by the date of the mother's last menstrual period, fundal height, ultrasonography, and an evaluation of the newborn with a standardized Ballard examination.14

Social history and demographic data were collected

during a structured interview. Labor and delivery information was recorded from medical records with a standardized data coding sheet.

Delivered placentas were placed on a clean surface; the chorion and amnion were separated manually by gloved personnel. Care was taken to prevent contamination of the exposed surfaces. Sterile Dacron swabs were rolled across the internal surface of the separated membranes and used to inoculate culture media as previously described.¹ Placentas that could not be sampled immediately were stored at room temperature to prevent killing of anaerobic microorganisms at low temperatures. All placentas were cultured ≤24 hours of delivery.

The fetal membranes were grasped with forceps, and a 2 to 3 cm strip was cut from the point of rupture to the discoid placental margin to prepare a "membrane roll" for histologic examination. A diagnosis of histologic chorioamnionitis was made if ≥ 10 polymorphonuclear leukocytes were present per field in 10 nonadjacent $400 \times$ fields as previously described.

The association of chorioamnion infection or inflammation with neonatal outcome was assessed only in the case group because the preponderance of neonatal morbidity and mortality occurs among infants born at ≤34 weeks' gestation. These data were collected from the medical records of the mother and neonate. Follow-up information was obtained by telephone interview 6 weeks after delivery. Infant death included stillbirths and neonatal deaths occurring ≤28 days after birth. Respiratory distress syndrome was defined as the requirement of supplemental oxygen to prevent cyanosis, the clinical observation of dyspnea, and the presence of air bronchograms and a reticulogranular pattern shown by a chest radiograph.

To examine the statistical significance of the membrane isolates with delivery at ≤34 weeks' gestation or with histologic chorioamnionitis, we used the p value associated with a Yates' corrected χ^2 statistic or a twosided Fisher exact test.15 A p value of 0.05 was considered to be statistically significant. To describe the relationship of chorioamnion bacteria and histologic chorioamnionitis with delivery at ≤34 weeks' gestation, we used an odds ratio as a point estimate of the excess risk. The adjusted odds ratios were determined and evaluated for statistical significance by logistic regression analysis.16 To determine the statistical significance of the odds ratio, we used 95% confidence intervals verified by likelihood ratio tests. Among the neonates delivered at ≤34 weeks' gestation, proportional hazards models developed by Cox17 were used to estimate the rate ratio of neonatal death associated with chorioamnion inflammation or infection. The outcome was neonatal death and the time to event was the number of days of life between birth and death. The relationship

The following characteristics were evaluated for their importance as confounding variables: race, marital status, education, gravidity, prior preterm birth, prior spontaneous abortion, referral source, smoking, alcohol use, delivery method, bacterial vaginosis, premature rupture of membranes, hours of membrane rupture, and hours of labor. CI, Confidence in-

of chorioamnion inflammation or infection with respiratory distress syndrome was evaluated among the surviving neonates by using Mantel-Haenszel stratified analyses with a risk ratio to provide the point estimate of excess risks.18

Results

Bacteria were recovered from 36 (32%) of 112 placentas delivered at ≤34 weeks' gestation and from 29 (19%) of 156 delivered at >34 weeks' gestation (unadjusted odds ratio 2.1; 95% confidence interval 1.1 to 3.8). Two or more bacteria were recovered from 17 (15%) of 112 placentas delivered at ≤34 weeks' gestation and 12 (8%) of 156 placentas delivered at >34 weeks' gestation (p = 0.05). Genital mycoplasmas were not related to delivery at ≤34 weeks' gestation. The recovery of bacteria other than U. urealyticum was related to preterm delivery at ≤34 weeks' gestation with and without placental membrane inflammation (Table I). Chorioamnion inflammation was highly related to delivery at ≤34 weeks, with and without chorioamnion bacteria. Inflammation and bacterial infection of the chorioamnion were independently related to delivery at ≤34 weeks, but each was most strongly related to preterm delivery in the presence of the other. None of the characteristics listed in Table I evaluated by logistic regression models as potential confounding variables altered the magnitude or significance of the relationship of inflammation and bacterial infections of the chorioamnion with delivery at ≤34 weeks' gestation.

Group B Streptococcus, Peptostreptococcus, and Fusobacterium recovered from the chorioamnion were associated with a preterm delivery at ≤34 weeks' gestation. U. urealyticum was recovered from similar proportions of preterm and term placentas (Table II). Anaerobic bacteria were recovered more often from placentas delivered at ≤34 weeks' gestation (18%) than from those delivered at >34 weeks' gestation (5%) (odds ratio 5.8; 95% confidence interval 2.0 to 20.5). Peptostreptococcus and Fusobacterium species were each significantly related to preterm birth, and Bacteroides species were weakly related to delivery at ≤34 weeks' gestation. Because of the infrequency of their isolation, it was not possible to assess whether placental Mycoplasma hominis, Actinomyces, Mobiluncus, or Candida species were associated with preterm birth. A lack of vaginal contamination was suggested by the low frequency of Lactobacillus isolated from the chorioamnion cultures.

Histologic chorioamnionitis was detected in 66 (59%) of 112 placentas delivered at ≤ 34 weeks' gestation and 35 (22%) of 156 placentas delivered at >34 weeks' gestation (unadjusted odds ratio 5.0; 95% confidence interval 2.8 to 8.8). Because the relationship between chorioamnion infection and inflammation was similar among both groups (data not shown), data were combined (Table III). U. urealyticum (which was not related to preterm birth) was strongly related to histologic chorioamnionitis. Group B streptococci and Fusobacterium were related to both preterm delivery and inflammation of the chorioamnion. Bacteroides and Escherichia coli were related to histologic chorioamnionitis. However, Peptostreptococcus (which was related to preterm birth) was not related to histologic chorioamnionitis.

To assess the neonatal risks associated with chorioamnion infection, we determined the frequency of death and respiratory distress syndrome among the 112 infants delivered at ≤34 weeks' gestation. Sixteen (14%) of the 112 infants died (Table IV). Microorganisms other than U. urealyticum were detected in the placentas of 10 (63%) of the infants who died and 26 (27%) of the 96 surviving preterm infants (rate ratio 3.8; 95% confidence interval 1.4 to 11.6). After adjustment for gestational age at delivery, the relationship lost statistical significance. Death occurred in 5 (45%) of 11 preterm neonates with E. coli or group B Streptococcus isolated from the chorioamnion. Of the 16 infants who died, 7 with birth weights <800 gm were stillborn, 3

^{*}U. urealyticum excluded.

with birth weights <1200 gm died within the first day of life, and 6 with birth weights <1200 gm had suspected sepsis and died of respiratory complications commonly associated with prematurity.

Respiratory distress syndrome developed among 43 (45%) of the 96 surviving neonates. Respiratory distress syndrome was weakly associated with chorioamnion infection by *Ureaplasma* or other bacteria and with histologic chorioamnionitis (Table V). After adjustment for gestational age at delivery, this association lost statistical significance.

Comment

The overlying hypothesis for this study was that upper genital tract infection represents one cause of preterm birth. Chorioamnion infection was related to preterm birth in this study after adjustments were made for duration of membrane rupture and labor and other demographic and behaviorial variables. The isolation of specific microorganisms from the chorioamnion was associated with delivery at ≤34 weeks' gestation and with histologic chorioamnionitis. Group B streptococci were associated with both delivery at ≤34 weeks' ges-

[†]Bacteroides species include B. bivius (2 cases), B. ureolyticus (1), B. asaccharolyticus (1), B. fragilis (1), and Bacteroides sp. (1).

tation and chorioamnionitis, and *E. coli* was significantly associated with histologic chorioamnionitis. These two microorganisms are the leading causes of neonatal sepsis and meningitis. ¹⁹ Our findings suggest that group B streptococci and *E. coli* are emerging as important placental pathogens.

Fusobacterium species have rarely been recovered from the chorioamnion in previous studies, although this organism is an important pathogen in the amniotic fluid of women in preterm labor who have intact membranes.11 Amniotic fluid Fusobacterium and Bacteroides bivius have also been significantly associated with delivery of infants weighing <2500 gm among women with intraamniotic infection.20 In our study Fusobacterium and Peptostreptococcus in the chorioamnion were associated with delivery at ≤34 weeks' gestation, and Fusobacterium and Bacteroides in the chorioamnion were associated with histologic chorioamnionitis. Anaerobes are infrequent isolates from neonates with suspected sepsis,19 although exceptions exist.21 Infant death among neonates with anaerobic infections of the chorioamnion could be related to preterm delivery or unrecognized neonatal infection with these bacteria, or it could be an indirect effect of toxins, inflammation, or suppressed leukocyte function.

U. urealyticum has long been recognized as a placental pathogen. Recovery of U. urealyticum from the cho-

rioamnion and newborn infant has been significantly related to histologic chorioamnionitis among term-delivered infants. U. urealyticum placental infection has been associated with prematurity, low birth weight, intrauterine growth retardation, and chorioamnionitis among preterm infants. Salation of U. urealyticum from the lower respiratory tract has been associated with chronic lung disease and death in very low birth weight infants. In our study, the recovery of U. urealyticum from the chorioamnion was related to histologic chorioamnionitis but not to delivery at ≤ 34 weeks' gestation. Our data suggest that infants exposed to U. urealyticum chorioamnion infection do not have increased mortality rates.

We defined prematurity as a gestational age of ≤ 34 weeks because evidence of chorioamnion infection and histologic chorioamnionitis is highest in the group delivered at ≤ 34 weeks' gestation. The prevalence of chorioamnion infection and histologic chorioamnionitis. is stable at > 35 weeks' gestation. Further, most of the morbidity and mortality related to prematurity occurs among infants born at ≤ 34 weeks' gestation. The relationship of chorioamnion infection and neonatal death could operate through the mechanism of infection causing prematurity. If this mechanism were established with certainty, adjustment for gestational age would not be appropriate. Never-

^{*}Time to event: number of days between birth and death.

[†]Adjusted for gestational age at delivery.

^{*}Adjusted for gestational age at delivery by Mantel-Haenszel stratified analysis.

theless, we elected to adjust for gestational age to examine whether chorioamnion infection per se was related to neonatal death independent of gestational age. Larger studies of placentas from preterm deliveries are needed to determine whether chorioamnion infection further increases the high neonatal death rate from prematurity in infants born at low gestational ages.

Chorioamnion infection is statistically related to histologic chorioamnionitis in this and several other studies. 1-3, 7, 8 However, some microorganisms in the placenta (U. urealyticum, group B Streptococcus, E. coli, Fusobacterium, and Bacteroides) appear to produce inflammation and others do not. The association between chorioamnion bacteria and prematurity is complex and does not simply relate to histologic inflammation: Peptostreptococcus in the chorioamnion was highly related to prematurity but not to histologic chorioamnionitis. U. urealyticum was related to histologic inflammation but not to delivery at ≤34 weeks' gestation. Further, only one third of chorioamnions with inflammation yielded microorganisms, and only 58% of infected chorioamnions had inflammation. Our data support the concept that histologic chorioamnionitis and infection are related but distinct entities.

It is not possible to demonstrate a cause-and-effect relationship between infection and preterm birth by using this study design; however, the data in this report suggest that only certain microorganisms in the chorioamnion are associated with preterm delivery. It is possible that certain bacteria primarily invade the chorioamnion, elicit an inflammatory response, and initiate labor leading to preterm delivery and that other microorganisms secondarily invade the chorioamnion during labor and are equally frequent among preterm and term women and in the chorioamnions with and without inflammation. Alternatively, it is possible that some microorganisms not independently associated with preterm birth play a role in preterm birth when present in combination with other bacteria. Larger studies will allow more detailed examination of the relationship between individual bacterial isolates and prematurity after adjusting for length of labor or membrane rupture.

Our data suggest that *U. urealyticum*, group B Streptococcus, E. coli, Bacteroides, Fusobacterium, and Peptostreptococcus should be considered as important placental pathogens associated with delivery at ≤34 weeks' gestation and histologic chorioamnionitis. Clinically useful methods to diagnose chorioamnion infections before delivery are not yet available. When these methods are developed, antibiotic therapy can be evaluated for efficacy in prolonging pregnancy among those women in preterm labor who have infections. The prevention of preterm delivery and neonatal sequelae by directed antibiotic therapy would support a primary rather than a secondary role of infection in preterm delivery.

Incidence and prevalence of human immunodeficiency virus infection in a prenatal population undergoing routine voluntary human immunodeficiency virus screening, July 1987 to June 1990

Michael K. Lindsay, MD, MPH, Herbert B. Peterson, MD, Susan Willis, MSN, Barbara A. Slade, MD, Joanne Gramling, RN, Harriet Williams, RN, and Luella Klein, MD

Atlanta, Georgia

To characterize the epidemiologic characteristics of human immunodeficiency virus type 1 infection in an urban prenatal population in the southeastern United States, we conducted serial routine voluntary antenatal human immunodeficiency virus antibody testing and obtained self-reported human immunodeficiency virus risk behavior profiles on women registering for prenatal care. From July 1987 to June 1990, 23,432 women registered for prenatal care. The majority of women (95%) consented to human immunodeficiency virus antibody testing and completed risk behavior profiles. The cumulative incidence of human immunodeficiency virus infection increased from 3.5 per 1000 in 1987 and 1988 to 5.3 per 1000 in 1989 and 1990. A history of "crack" cocaine use emerged as a significant risk factor for infection (p < 0.01). The majority (70%) of human immunodeficiency virus—infected women did not self-acknowledge risk factors for infection and would not have been identified if screening had been targeted. The increasing incidence of human immunodeficiency virus type 1 infection in our prenatal population reinforces the need for our continued routine voluntary antenatal human immunodeficiency virus screening and risk behavior assessment. (AM J OBSTET GYNECOL 1991;165:961-4.)

Key words: Incidence of human immunodeficiency virus infection, voluntary antenatal antibody screening, "crack" cocaine

From 1988 to 1989 the Centers for Disease Control (CDC) reported a 29% increase in cases of acquired immunodeficiency syndrome among women. In 1990 women represent the group with the fastest rate of increase in human immunodeficiency virus (HIV) infection and will account for 11% of cases of acquired immunodeficiency syndrome in the United States. The consequences of increasing HIV infection could potentially be devastating, for women, for their sex partners, and for their infants. For their sex partners, and for their infants.

The incidence of HIV infection in pregnancy and risk behaviors for infection have been poorly characterized. Most published studies to date have been blinded surveys that failed to link serologic prevalence with risk behaviors. Find This report describes the results of 3 years of routine voluntary antenatal HIV antibody screening and linked risk behaviors. The objectives of this study are twofold: to monitor the incidence of HIV infection in women who receive prenatal care at our institution and to characterize the risk behavior for infection. Because of our policy of routine voluntary HIV screening we have the unique opportunity to conduct this epidemiologic survey in a large, well-characterized subset of women of reproductive age.

Material and methods

Patients. Between July 1, 1987, and June 30, 1990, a study of HIV incidence in prenatal patients was con-

ducted at Grady Memorial Hospital. Grady Memorial Hospital is a 1000-bed county hospital in Atlanta, which provides care for a predominantly black inner-city population. During the study period there were 23,587 deliveries and 4500 abortions.

The framework of routine voluntary antepartum HIV screening in 1987 and 1988 has been described in a previous report.¹⁰ In 1988 and 1989 each woman received information prepared by the Georgia Department of Human Resources on acquired immunodeficiency syndrome and HIV testing11 before granting informed consent. In 1989 and 1990 the pretest counseling material was supplemented by 30 minutes of HIV counseling. Patients were counseled in small groups of 5 to 7. All counseling sessions were conducted by trained HIV counselors. Before counseling all women were asked to complete a self-administered questionnaire, which assessed risk factors for infection. In addition, after being informed of infection, all women with seropositive results were asked to complete an in-depth questionnaire assessing risk factors for infection.

Laboratory. Specimens were screened for HIV-1 antibody with a commercial solid-phase enzyme immunoassay (Abbot HTLV-III EIA; Abbot Laboratories, North Chicago) according to the manufacturer's assay protocol. Specimens that were repeatedly reactive by this assay were examined by Western blot technique (Biotech DuPont HTLV-III Western blot kit, DuPont Pharmaceuticals, Wilmington, Del.). Specimens with

reactivity to any antigen band in two of three viral gene product groups were considered HIV-1 seropositive.

Data analyses. Clinical and demographic data were recorded onto computer tape and machine edited. The estimated incidence rate is expressed as the number of HIV-1—positive specimens divided by the total number tested for that year. Seropositive women identified prior to pregnancy were not included in incidence calculations. Statistical analysis included χ^2 test, which measured differences between proportions. Significance is expressed at the 0.05 level.

Results

During the 3-year study period 23,432 pregnant women registered for prenatal care; 22,364 (95.4%) consented to HIV antibody testing and completed the self-administered HIV risk behavior questionnaire. Of the 22,364 women screened for HIV infection 113 (5.0/1000) had seropositive results by Western blotsupplemented testing. The yearly cumulative incidence of HIV infection increased from 3.5 per 1000 in 1987 and 1988 to 5.3 per 1000 in 1989 and 1990, which was not significant. Three women were known to be HIV infected before pregnancy. All women but one had asymptomatic HIV infection. The racial, marital, and educational status of seropositive and seronegative women was similar. However, the age distribution was significantly different (p < 0.05) (Table I). This is accounted for primarily by the larger percentage of seropositive results in women in the 21- to 25-year age

NS, Not significant.

group. There was a significant increase in self-reported HIV risk behavior from 9.4% in 1987 and 1988 to 15.2% in 1989 and 1990 (p < 0.05). The increase in self-reported risk behavior is attributable in part to significant increases in HIV-infected sexual partners and use of "crack" cocaine (p < 0.01) (Table II). During the 3-year study interval, risk factors for HIV infection among women with seropositive results were nearly comparable except for a significant increase in "crack" cocaine use (p < 0.01) (Table III). Before HIV antibody testing, 34 (29.1%) women with seropositive results acknowledged risk factors for infection. After being informed of their serologic status, an additional 29 (25.7%) women acknowledged risk factors for infection.

During the 3-year study interval, 10 of 57 (17.5%) women with seropositive results who were eligible for abortion by gestational age criteria terminated their pregnancies.

Comment

Incidence data on HIV infection in women of reproductive age are extremely important. These data may assist public health officials in projecting health expenditures for HIV-related care and planning prevention strategies. During the 3-year study period we found a 1.5-fold increase in incidence of HIV infection among women registering for prenatal care. The increasing incidence likely represents increasing infection in pregnant women in our community.

The prevalence of HIV infection of 5.8 per 1000 in childbearing women seen at Grady Memorial Hospital in 1988 to 1990 was 3.6-fold higher than the 1.6 per 1000 childbearing women reported from statewide heel stick data from Georgia.9 In addition, the cumulative incidence of HIV infection of 5 per 1000 pregnancies is 3.5-fold higher than the CDC's 1989 national seroprevalence estimates that are based on cord blood testing of 1.5 per 1000 childbearing women.9 On the basis of the current annual incidence of HIV infection in our institution and assuming either a decreasing or stable rate of infection, we estimate that 35 to 40 pregnant women per year who register for prenatal care will be HIV infected. However, it is possible that the incidence of HIV infection will continue to increase, yielding >40 HIV-infected pregnant women per year.

Risk behaviors in HIV-infected parturients provide important insights about potential mechanisms of spread of infection. A disturbing finding was the approximate doubling of self-reported HIV risk behavior over time. The increase in risk behavior closely parallels the increase in incidence. From our analysis there ap-

^{*}Risk factors are assumed to be mutually exclusive.

pears to be an emerging relationship between increase "crack" cocaine use and HIV infection. During the 3year study interval we observed a sixfold increase in self-reported "crack" cocaine use among all parturients. In addition, we found a fivefold increase in "crack" cocaine use as a potential risk factor for infection among HIV-infected pregnant women. "Crack" cocaine use is believed to increase sexual risk taking and is likely to increase HIV risk by this mechanism.

In this study self-selection bias was minimized, as 95% of parturients eligible for screening consented to antibody testing and completed risk behavior questionnaires. In this as in other studies6, 10, 12 there was a poor correlation between targeted screening and HIV infection. Nearly three fourths of seropositive pregnant women had no self-identified risk factors for infection and would not have been identified if our policy of routine voluntary antibody screening had not been in place. Our 3-year experience has shown us that routine voluntary antenatal HIV screening is a valuable component of comprehensive prenatal care. We believe that such testing must be offered on a voluntary basis, with written informed consent with ensured confidentiality,10 and without impeded access to prenatal care. Through such screening 112 HIV-infected women without symptoms were detected during the study interval. These women were educated about the major modes of virus transmission, encouraged to practice risk-reduction behavior, provided contraceptives, and referred for both pediatric and adult infectious disease follow-up. The identification of HIV-infected women without symptoms has immediate urgency in light of the recent clinical trials that reveal benefits of low-dose zidovudine in asymptomatic HIV infection.13

In spite of the known risk of perinatal transmission of HIV infection, 84% of infected women eligible to have elective abortions declined the procedure. Therefore in our institution termination of pregnancy in HIV-infected women will be chosen infrequently as a means to prevent perinatal transmission.

These data represent the first report of the estimated incidence of HIV infection in a large, well-characterized prenatal population. Our findings are a direct indication of the growth of the epidemic in our community.

Natural killer cell cytotoxicity to herpes simplex virus-1-infected cells is not altered by pregnancy

Nancy L. Eriksen, MD, Bernard Gonik, MD, and Lian S. Loo, MS Houston, Texas

There is evidence to suggest a decrease in natural killer cell cytotoxicity during pregnancy, but information regarding immune responsiveness to actual infection is limited. An in vitro study was undertaken to examine the effect of herpes simplex virus infection on natural killer cell cytotoxicity with peripheral blood mononuclear cells from pregnant (N=8) and nonpregnant (N=5) women. The peripheral blood mononuclear cells were separated by Ficoll-Hypaque centrifugation. Effector cells were incubated with live herpes simplex virus-1, ultraviolet-inactivated herpes simplex virus-1, or media alone for 18 hours at 37° C. K562 target cells were used in a sodium chromate release assay with an effector-to-target cell ratio of 100:1. Baseline natural killer cell values (mean \pm SE) for pregnant patients (13.4% \pm 2.4%) and nonpregnant patients (19.8% \pm 3.7%) were similar. Natural killer cell cytotoxicity was significantly increased by incubation with live virus for both pregnant (37.5% \pm 6.2%) and nonpregnant subjects (49.8% \pm 7.6%). There was no difference in mean values between media and ultraviolet-inactivated herpes simplex virus-1-exposed samples for either group. Results suggest that (1) infection with live virus, but not viral antigen alone, can augment natural killer cell response in vitro and (2) natural killer cell response to herpes simplex virus-1 infection is not altered by pregnancy. (AM J OBSTET GYNECOL 1991;165:965-8.)

Key words: Natural killer cell cytotoxicity, herpes simplex virus, pregnancy

Natural killer cells are distinct from cytotoxic T lymphocytes in their ability to lyse target cells without prior antigenic sensitization. Therefore they play a primary role in the immune defense system against viral infection, including herpes simplex virus (HSV).

Several reports suggest that pregnant women have a higher incidence of HSV infection, with a longer duration and severity of clinical symptoms.¹⁻⁴ However, epidemiologic data to support this suggestion are lacking.⁵ Several authors have shown a decrease in natural killer cell cytotoxicity in pregnant subjects compared with nonpregnant controls.⁶⁻¹² This has led some investigators to refer to pregnancy as an immunocompromised state. There is limited information regarding natural killer cell immune responsiveness to actual infections in humans.

An in vitro study was undertaken to examine the effect of HSV infection on natural killer cell cytotoxicity with peripheral blood mononuclear cells from pregnant and nonpregnant subjects. We hypothesized that natural killer cell cytotoxicity would be augmented by HSV infection in a similar fashion for both groups.

Material and methods

Patients. After written informed consent was obtained, 20 ml of blood was obtained into heparinized tubes from eight pregnant subjects and five reproductive-aged nonpregnant controls.

Preparation of effector cells. Dextran (3%, Sigma Chemical Co., St. Louis) was added to each tube (10%, vol/vol) and allowed to sediment for 45 minutes. The plasma was then placed over 10 ml of Ficoll-Hypaque (Pharmacia Laboratories, Inc., Piscataway, N.J.) and centrifuged at 200 g for 45 minutes. The mononuclear cell layer was washed three times in Hank's balanced salt solution (Hazelton, Lenexa, Kan.) and resuspended in 1 ml minimal essential media (Gibco Live Technologies, Grand Island, N.Y.) supplemented with 10% heat-inactivated fetal calf serum (Hazelton), penicillin (50 U/ml), and streptomycin (50 μg/ml). These mononuclear cells are a heterogeneous cell population consisting of lymphocytes, macrophages, and natural killer cells.

Target cells. K562 (an erythroleukemia cell line) target cells were grown in culture. A pellet was obtained by centrifuging 10 ml at 200 g for 5 minutes. The pellet was resuspended in 150 μ l of 10% minimal essential media and incubated with 20 to 80 μ l sodium chromate (Dupont, Wilmington, Del.) for 1 hour at 37° C. The cells were then layered over 3 ml heat-inactivated fetal calf serum and centrifuged for 5 minutes at 200 g. The pellet was then washed with 10 ml 10% minimal essential media. The supernatant was discarded, 1 ml of 10%

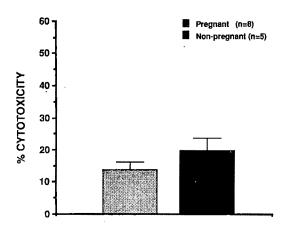

Fig. 1. Baseline natural killer cell cytotoxicity (mean \pm SE) in pregnant and nonpregnant subjects (p=0.25). Effector/target cell ratio equals 100:1.

minimal essential media was used to resuspend the pellet, and the cells were counted. The sodium chromate–labeled target cells were suspended at a final concentration of 1×10^5 cells per milliliter in 10% minimal essential media.

Microcytotoxicity assay. Each assay was conducted in triplicate in polystyrene U-bottom-well microtiter plates (Corning, Corning, N.Y.). The unstimulated wells, for pregnant and nonpregnant subjects, consisted of 50 µl effector cells and 50 µl 10% minimal essential media, yielding a final concentration of 5×10^6 cell per milliliter. Each of the HSV-stimulated wells consisted of 50 µl effector cells and 50 µl either live HSV-1 virus (2 × 10⁵ plaque-forming units) or 50 μl ultravioletinactivated HSV-1 (2 × 10⁵ plaque-forming units). The final concentration of effectors was 5 × 106 cells per milliliter with 1×10^5 plaque-forming units of HSV. The cells were incubated for 18 hours at 37° C. Experimental wells that contained live virus were washed, along with the unstimulated wells, three times with 10% minimal essential media. Subsequently, 50 µl of 10% minimal essential media and 50 µl of labeled target cells $(1 \times 10^{5} \text{ cells per milliliter})$ were added to all of the wells. The final effector-to-target cell ratio was 100:1. The covered plate was then centrifuged at 75 g for 5 minutes and allowed to incubate an additional 4 hours at 37° C in a humidified atmosphere of air (95%) and carbon dioxide (5%). Afterward 100 µl was aspirated from the top of each well without disturbing the pellet. To each well, 100 µl of 1 mol/L sodium hydroxide was added, and the total volume was aspirated into a separate tube. The samples were counted in a Packard Cobra 5010 y-counter for 1 minute. Chromium release was calculated by the formula:

$$\frac{\text{Percent sodium}}{\text{chromate release}} = \frac{2A}{A + B} \times 100$$

where A equals counts per minute in the top 100 μ l

and *B* equals counts per minute of the lysed pellet.

Natural killer cell cytotoxicity equals:

$$\frac{\text{Experimental release} - \text{Spontaneous release}}{100 - \text{Spontaneous release}} \times 100$$

Data are expressed as the mean \pm SE of experiments. These data were analyzed with the arcsine transformation. Comparisons were made between the two groups by the analysis of variance, with p < 0.05 considered statistically significant.

Results

Baseline natural killer cell cytotoxicity (mean \pm SE) was lower in pregnant subjects (13.8% \pm 2.4%) than in nonpregnant subjects (19.8% \pm 3.7%) (Fig. 1). However, this did not reach statistical significance (p=0.25). Incubation of effector cells with live HSV-1 significantly increased natural killer cell cytotoxicity for pregnant (37.5% \pm 6.2%) and nonpregnant (49.8% \pm 7.6%) subjects, when compared with values for media alone (Fig. 2). As anticipated, the increase in cytotoxicity was similar for both groups (p=0.25) (Fig. 2).

Similar experiments with ultraviolet-inactivated HSV-1 (1×10^5 plaque forming units) showed no difference in mean natural killer cell cytotoxicity values (Fig. 3) when compared with those for media alone for either group. Additional experiments were conducted with 1×10^7 plaque forming units of ultraviolet-inactivated HSV-1, to determine if increasing the amount of antigen would have any effect on cytotoxicity. Again, no difference in mean natural killer cell cytotoxicity values were noted for either group (results not depicted).

Comment

Pregnancy represents a unique immunologic state in which a balance exists between acceptance of the fetal allograft and host immunocompetence. A suppression in maternal cell-mediated immunity is assumed to be advantageous for the fetus but theoretically makes the pregnant woman more vulnerable to infections, particularly those of viral causes. Case reports^{3, 4} and animal work¹³ suggest that the severity of an HSV infection is increased in pregnancy. A higher incidence of HSV infections and a longer duration of clinical symptoms have been reported in pregnancy. Although firm epidemiologic data are lacking to confirm these observations,⁵ these clinical reports have led to the suggestion that pregnancy is an immunocompromised state.

Natural killer cells represent the first line of defense against viral pathogens and therefore play an important role in HSV infection. Data in regard to natural killer cells in pregnancy are limited and sometimes conflicting. Histochemical studies⁹ and flow cytometry¹⁰

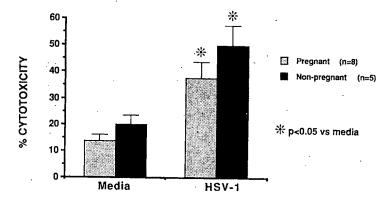

Fig. 2. Natural killer cell cytotoxicity in response to live HSV-1 infection. Results (mean \pm SE) show pregnant and nonpregnant subjects compared with controls (media alone, p < 0.05). Effector/target cell ratio is 100:1.

have shown that the number of natural killer cells is not reduced during pregnancy. Natural killer cell function has been examined in several recent studies, 7-12 which demonstrate a general decrease in natural killer cell activity during pregnancy, although this finding is not consistent. None of these previous studies have attempted to examine the effect of actual infection on natural killer cell immune responsiveness.

To address this question, an in vitro model was developed in which peripheral blood mononuclear cells: of pregnant and nonpregnant subjects were infectedwith live HSV-1 virus. Natural killer cell cytotoxicity was measured in control and infected wells to determine if pregnancy altered immune responsiveness to infection. Our results in Fig. 1 show that baseline cytotoxicity tended to be lower in pregnant subjects, compared with nonpregnant controls. Although this did not reach statistical significance, the calculated power of these experiments (0.54) to reveal a significant reduction in natural killer cells (20%) is limited. To have a power = 0.8, 14 paired experiments would need to be analyzed. Regardless, our results are consistent with data already available in the literature7-12 and are not central to the issue of HSV-induced immune responsiveness. Incubation of effector cells with live HSV-1 resulted in a significant increase in natural killer cellcytotoxicity as compared with controls for both groups (Fig. 2). There was a 2.5-fold increase in cytotoxicity in the nonpregnant subjects, compared with a 2.7-fold increase in the pregnant subjects. This demonstrates that, in spite of lower baseline natural killer cell cytotoxicity values in the pregnant subjects, they were able to respond in a similar fashion as the nonpregnant subjects (Fig. 2).

Viral infection leads to the production of a variety of cytokines. Several of these cytokines, in particular interferon alfa, are known to regulate natural killer cell function. Deficiencies in cytotoxic responses have been shown to result in a greater susceptibility to HSV in-

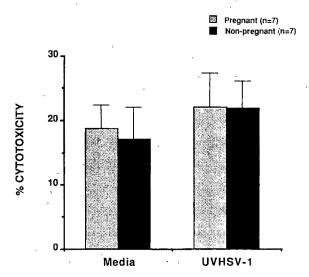

Fig. 3. Natural killer cell cytotoxicity in response to ultraviolet-inactivated HSV-1. Effector/target cell ratio is 100:1.

fection.^{14, 15} Furthermore, natural killer cell activity aginst HSV infection is enhanced by interferon in vitro, ^{16, 17} and in vivo. ¹⁸ Data from our laboratory confirm that interferon alfa can augment natural killer cell cytotoxicity in the pregnant host. ¹⁹

One could speculate that, although baseline natural killer cell activity during pregnancy may be decreased, cytokine production in response to infection may be normal, accounting for our results. Evidence to support this includes the ability of interferon to restore natural killer cell activity from peripheral blood of pregnant patients, 10 and systemic interferon production is higher in pregnant mice than in controls. 13 Surprisingly, few data regarding cytokine production in human pregnancy exist. Studies examining the production of interleukin-120 and interleukin-221 demonstrate elevated or normal production rates, respectively, compared

with those of nonpregnant controls. We have shown that the monokines tumor necrosis factor and interleukin-6 also are significantly increased during pregnancy (unpublished observations). Although interferon alfa has not been directly measured during pregnancy, these data support the concept that its production during pregnancy is unchanged.

Interestingly, we found that ultraviolet-inactivated HSV-1 did not augment natural killer cell activity as did infection with live virus (Fig. 3). This suggests that infection with live virus may be necessary to induce the intracellular production of interferon alfa. Kirchner et al.22 demonstrated that interferon alfa could be detected after injection of live herpesvirus in mice but not with ultraviolet-inactivated herpes antigen. However, HSV antigen in much higher concentrations, and with extended incubation, has been shown to induce lymphocyte stimulation in previously sensitized cells.^{23, 24} The mechanism for this induction has not been identified, but it is most likely humoral in origin. Data from lymphocyte stimulation experiments cannot be extrapolated to explain natural killer cell function, because natural killer cells lyse target cells without prior antigenic sensitization.

In conclusion, our results suggest that (1) infection with live virus, but not viral antigen, can augment natural killer cell cytotoxicity in vitro and (2) natural killer cell response to HSV-1 infection is not altered by pregnancy. We speculate that, during pregnancy, the production of interferon alfa is not attenuated in response to infection with live herpesvirus. This could explain the increase in natural killer cell cytotoxicity in vitro observed in both pregnant and nonpregnant subjects. Although our data suggest that isolated mononuclear cells respond appropriately to HSV infection during pregnancy, other factors, such as serum-mediated suppression of immune activity, may alter in vivo host responses.

Systemic administration of interleukin-1 induces preterm parturition in mice

Roberto Romero, MD, Moshe Mazor, MD, and Boris Tartakovsky, PhD

New Haven, Connecticut, and Beer Sheva and Rehovot, Israel

Interleukin-1 has been postulated as a signal for the initiation of preterm labor and delivery. Interleukin-1 is produced by human decidua, stimulates prostaglandin production by intrauterine tissues, and is present in the amniotic fluid of women with preterm labor and intraamniotic infection. The purpose of these studies was to determine whether interleukin-1 could induce parturition in an animal species. Timed-pregnant C3H/HeJ inbred mice (n=24) (genetically endotoxin resistant) were randomized to receive either recombinant human interleukin-1 or sterile phosphate-buffered saline solution between days 15 and 17 of gestation (normal length of pregnancy, 20 to 21 days). Three consecutive subcutaneous injections of interleukin-1 or phosphate-buffered saline solution were administered within 6 hours. Examinations of the animals were performed by blinded observers. Parturition occurred within 24 hours in all of the interleukin-1—treated mice and in none of the control group. Vaginal bleeding was first noted 4 hours after the first interleukin-1 injection, and delivery began within 12 hours after the last interleukin-1 injection. Premature delivery occurred in all interleukin-1—injected mice. Laparotomy revealed that there were no remaining fetuses in utero. All mice in the control group delivered spontaneously between days 20 and 22. We conclude that systemic administration of interleukin-1 induces preterm labor and delivery in mice. (AM J OBSTET GYNECOL 1991;165:969-71.)

Key words: Interleukin-1, cytokines, parturition, labor, chorioamnionitis, prematurity, preterm labor, mice

There is a strong association between systemic or intrauterine infection and preterm labor and delivery (reviewed in reference 1). It has been estimated that at least 20% of preterm births occur in women with microbial invasion of the amniotic cavity.2 However, the mechanisms responsible for the initiation of parturition in the setting of infection have not been elucidated. Interleukin-1 (IL-1), a cytokine produced by human decidua in response to bacterial products,8 has been proposed as a signal for the initiation of labor in the setting of infection.4 Although IL-1 stimulates prostaglandin production by human amnion⁵ and decidua⁶ and is present in the amniotic fluid of women with preterm labor and microbial invasion of the amniotic cavity, there is no direct evidence that this cytokine can induce parturition.4 The purpose of these studies was to determine whether systemic administration of IL-1 can induce parturition in mice.

Material and methods

Animals. Mice were selected as the experimental animal because of the investigators' familiarity with murine reproductive biology and the considerable information available regarding the immune system and cytokine physiology in this species. Studies were conducted with 19-week-old C3H/HeJ mice that were impregnated by C57BL/6J X DBA/2 F-1 male mice. Animals were allowed free access to food and water before and during experimentation and were exposed to a 12-hour-light/12-hour-dark cycle. Under these conditions mating occurs during the mid—dark period. Mating date, as evidenced by vaginal plug, was designated day 1 of pregnancy.

Experimental design. Twenty-four mice were randomized to receive human recombinant IL-1 α (Hazelton Laboratories, Baltimore) (n=12) or sterile phosphate-buffered saline solution (n=12) subcutaneously. Gestational ages were 15 days (n=12), 16 days (n=4), and 17 days (n=8). Normal duration of pregnancy in this mating combination is 20 to 21 days. Randomization was stratified for gestational age.

Injections consisted of 1 μ g of IL-1 α diluted in 100 μ l of sterile phosphate-buffered saline solution or 100 μ l of phosphate-buffered saline solution. The endotoxin content of this preparation of IL-1 α is <0.1 ng/mg protein (determined with the limulus amebocyte lysate assay). IL-1 α , rather than IL-1 β , was selected for these experiments because IL-1 α is the main IL-1 spe-

1 /	Time							
Gestational age	4:40 PM	5:20 РМ	7 PM	7:45 PM	12 Midnight			
Day 15 $(n = 6)$	1 .	3	4	5	5*			
Day 16 $(n = 2)$	2	2	2	2	2			
Day 17 (n = 4)	0	0	0	3	3			

Table I. Frequency of vaginal bleeding according to gestational age in animals receiving IL-1

cies produced by murine macrophages. The dose of IL- 1α selected for these experiments has been shown to be optimal for the induction of an acute-phase response in mice.⁷ Injections were performed at 12 noon, 2:15 PM, and 5:30 PM. The investigators observing the animals were blinded to the treatment protocol.

Results

Behavioral changes (piloerection and lethargy) were noted at the time of the second injection in all IL- 1α treated animals and in none of the control animals. At the time of the third injection one mouse (15 days' gestation) injected with IL-1α became prostrate. Six hours later this mouse was found dead. Vaginal bleeding was first noted 2 hours after the second injection in animals injected with IL-1a. Table I describes the occurrence of vaginal bleeding over time in the IL-1αtreated group. No animals receiving phosphate-buffered saline solution had vaginal bleeding.

Preterm delivery occurred in all 11 IL-1α-treated animals but in none of the phosphate-buffered saline solution-treated group. Within 12 hours of the last injection all IL-1-treated mice were in the process of delivery. Within 24 hours after the last injection 41 dead, premature, newborn mice were counted in the cages. However, several mothers were observed eating recently passed fetuses. Hysterotomy was performed 48 hours after the last injection. No fetuses were found in utero.

Deliveries in the control group occurred on day 20 in all female mice but one. A total of 83 newborn mice were counted. Four were stillborn or died shortly after birth. One mouse, injected on day 15 of pregnancy, delivered four newborn mice on day 22 (three were stillborn and one died 3 days later).

Comment

The traditional paradigm invoked to explain the onset of labor in the setting of infection has been that bacterial products directly stimulate prostaglandin biosynthesis.8 Indeed, bacteria are a source of phospholipase A28 and C,9 and bacteria-conditioned media can stimulate prostaglandin production by human amnion. 10-13 Moreover, lipopolysaccharide, a component of the cell wall of gram-negative bacteria, is frequently

present in the amniotic fluid of women with intraamniotic infections14 and is capable of stimulating prostaglandin production by amnion15 and decidua.16 Additionally, the amniotic fluid concentration of endotoxin in women with preterm labor and premature rupture of membranes was higher than in women with premature rupture of membranes without labor.17

In spite of these data, there is evidence that bacterial products alone are not responsible for the onset of preterm labor in the setting of infection. First, one third of women with preterm premature rupture of membranes without labor have microbial invasion of the amniotic cavity,1 suggesting that the mere presence of microorganisms in the amniotic cavity is not sufficient to lead to the onset of labor. Second, it is now apparent that the effects of microbial products on prostaglandin production by intrauterine tissues are highly dose dependent and often inhibitory.18

The recognition of the key role played by cytokines in the pathophysiologic characteristics of fever, endotoxic shock, and other metabolic derangements associated with infection prompted us to propose that the initiation of labor in the setting of infection could be mediated by cytokines. The evidence to support a role for IL-1 includes the following: (1) IL-1 stimulates prostaglandin production by amnion⁵ and decidua⁶; (2) human decidua can produce IL-1 in response to bacterial products3; (3) amniotic fluid IL-1 bioactivity and concentrations are elevated in women with preterm labor and microbial invasion of the amniotic cavity4; (4) in women with preterm premature rupture of membranes and microbial invasion of the amniotic cavity, amniotic fluid IL-1 bioactivity and concentrations are significantly higher in patients with labor than in those without labor,4 indicating that the secretion of IL-1 into the amniotic fluid is associated with parturition rather than infection; (5) in vitro perfusion of human uteri with IL-1 elicits uterine contractility (Bulletti C, Romero R. Unpublished observations).

The results of the experiments described in this communication indicate that systemic administration of IL-1 induces preterm parturition in mice. The results provide strong support for the view that cytokines may play a role in the onset of parturition. We assume that IL-1 binds to IL-1 receptor-bearing cells within the

^{*}One mouse died.

uteroplacental tissues and induces a cascade of biochemical events leading to uterine muscle contraction and active delivery of premature fetuses. Our observations are apparently at variance with those reported by Silen et al. 19 and Parant. 20 Silen et al. reported fetal death and necrosis of the placenta and decidua after administration of a single injection of IL-1α (100 to 500 µg/kg) to 12-day pregnant rats. However, abortion or premature labor did not occur. Similarly, Parant20 reported fetal death (100% of cases) and some preterm deliveries (rate not stated in the report) after a single intravenous injection of 10 µg per mouse to 12-daypregnant mice. The most obvious differences between these reports and ours are the dose and the timing of IL-1 administration.

The current study is relevant to the occurrence of parturition in cases of systemic febrile illnesses in which IL-1 can be detected in the peripheral circulation. However, further studies are required to establish whether intrauterine administration of cytokines can induce parturition. Such an experimental approach would address the issue of whether increased local intrauterine availability of IL-1 can also induce parturition. Although our results indicate that IL-1 can induce parturition in mice, they do not address the issue of whether IL-1 is a requirement for parturition in the setting of infection. Recently, IL-1 receptor antagonists have become available and should be helpful in testing this hypothesis and also in determining whether the effect of IL-1 in the induction of parturition is receptor mediated.

Prophylactic amnioinfusion as a treatment for oligohydramnios in laboring patients: A prospective, randomized trial

David B. Schrimmer, MD, Charles J. Macri, MD, and Richard H. Paul, MD Los Angeles, California

Prophylactic amnioinfusion was studied in a randomized sample of 305 patients with oligohydramnios in labor. One hundred seventy-five patients underwent amnioinfusion with the remainder serving as controls. Amniotic fluid was titrated to an amniotic fluid index >10.0 cm in the treatment group. Patients receiving amnioinfusion had significantly less operative intervention for fetal distress (p=0.0001) and fewer cesarean sections (p=0.0001). Umbilical artery pH at the time of delivery also was increased (p=0.0001). Rates of amnionitis and endometritis were not significantly different between infused patients and controls, although the length of hospital stay was significantly decreased (p=0.002) in the treatment group. Our data support earlier reports in the literature that amnioinfusion is a useful technique for decreasing intrapartum morbidity for both mother and fetus. (AM J OBSTET GYNECOL 1991;165:972-5.)

Key words: Amnioinfusion, amniotic fluid index, operative intervention, fetal distress

Amnioinfusion is being used for several indications, including prophylactic treatment of oligohydramnios, elimination of significant variable decelerations in labor,1-3 and the prevention of meconium aspiration in laboring patients with thick meconium.4 Initial studies in the literature have been promising, with decreased operative intervention for fetal distress and improved neonatal outcome reported.5 These findings are believed to be due to the restored cushioning effect of amniotic fluid and the subsequent prevention of cord compression. These initial studies, however, have raised questions about the use of amnioinfusion in statistically reducing the incidence of cesarean section for fetal distress and the relationship between amnioinfusion and intrapartum or postpartum infection.5,6 The purpose of this study was to examine the effect of prophylactic amnioinfusion on the incidence of operative intervention for fetal distress, the fetal outcome, and its effect on the incidence of intrapartum and postpartum infection.

Material and methods

Between Aug. 1, 1989, and Sept. 15, 1990, 305 patients at Los Angeles County/University of Southern California Women's Hospital were studied in a prospective, randomized fashion. Patients were initially identified as having oligohydramnios on admission on the basis of a four-quadrant amniotic fluid index of <5.0 cm at the time of admission.⁷ Patients either were

in labor or were being admitted for induction of labor because of oligohydramnios. Membranes could be either intact or spontaneously ruptured on admission. Criteria for enrollment also included a singleton gestation, vertex presentation, and normal fetal heart rate baseline and variability. Exclusion criteria included moderate or severe variable decelerations, late decelerations, vaginal bleeding, fetal anomalies, and chorioamnionitis. Patients were not excluded because of the presence or absence of meconium. Once enrolled, patients were not excluded from the study, nor were they randomized to any other studies. Eligible patients who agreed to participate in the institutional review board—approved study were enrolled after providing written informed consent.

After enrollment, patients were prospectively randomized to a treatment group (amnioinfusion) or a nontreatment group. Randomization was done by computer randomization and sequentially numbered opaque, sealed envelopes. The ratio of treatment to nontreatment groups was 3:2. The 3:2 ratio was chosen to encourage enrollment. Study design included power calculations that were based on an α error of 0.05 to establish statistical significance and a β error of 0.20. Calculations showed that a minimum of 114 patients were required in each arm, on the basis of the differential rate of cesarean delivery because of fetal distress (13% vs 3%) and the difference in the incidence of amnionitis (20% vs 7%) as reported by Strong et al.5 in an earlier study completed at our institution.5

After adequate cervical dilation had been achieved, patients had an intrauterine pressure catheter inserted, through which those patients in the amnioinfusion group received an infusion of 500 ml normal saline solution at 37° C. Saline solution was infused by gravity

flow over 20 to 30 minutes (15 to 25 ml/min). After the initial infusion, ultrasonography was performed to measure the amniotic fluid index and confirm adequate restoration of intrauterine fluid volume (amniotic fluid index, ≥10.0 cm). If the amniotic fluid index was found to be ≥10.0 cm, no further fluid was added. If the amniotic fluid index was ≥5.0 cm and <10.0 cm, an additional 250 ml was given, and if the amniotic fluid index was <5.0 cm, 500 ml was again given after intrauterine catheter placement was checked. Ultrasonography was repeated hourly, with the above-noted schedule followed to maintain an amniotic fluid index of ≥10.0 cm. Patients were allowed to labor, and on delivery cord gas values were obtained. Infants and parturients were monitored for signs of infection or other complications until discharge from the hospital.

It should be noted that the study was not blinded, because of the need for hourly ultrasonographic examinations and reinfusion in some patients. In an effort to eliminate bias, managing physicians were not the clinical investigators.

After completion of the study, data from all patients were included and reviewed. Tests for statistical comparison included the χ^2 , Mann-Whitney U, and Student t test.

Results

After enrollment and randomization, 305 patients were studied. One hundred seventy-five patients underwent amnioinfusion, and 130 patients served as a control group. Comparison of the treatment group versus the control group revealed no statistical differences between the groups with regard to age, parity, gestational age, initial cervical examination or admission amniotic fluid index (Table I).

In the infusion group patients received an average of 1.2 ± 0.5 infusions and an average volume of 554 ml (± 122 ml). Average increase in amniotic fluid index with the initial 500 ml infusion was 8.4 ± 1.4 cm. ·Twenty-three patients required more than one infusion, while 152 needed just the initial 500 ml bolus. In those requiring a second infusion, the average time to that infusion was 4.6 ± 1.6 hours. There were no infusion failures, although the intrauterine pressure catheter had to be replaced in three patients. No infusions had to be stopped because of fetal distress.

Comparison of the delivery methods between the infusion group and the control group shows significant differences in the overall incidence of cesarean section, total operative deliveries, operative deliveries for fetal distress, and cesarean section for fetal distress (Tables II and III).

Neonatal outcome revealed a significant difference in cord pH between the two groups, although 5-minute Apgar scores were not significantly affected (Table IV). Amnioinfusion did not appear to have any adverse effect on the fetus. None had seizures in the newborn period after the amnioinfusion, and there were no

other newborn problems associated with the procedure.

The incidence of both amnionitis and endometritis was not significantly different between the infusion and the control group. Interestingly, the length of hospital stay was significantly longer in the control group, a reflection of the increased rate of operative deliveries observed in this group (Table V).

Comment

The role of amniotic fluid in providing a cushion for the fetal umbilical cord has now been suggested by several authors.^{5, 8} The results obtained in our study provide further evidence that the maintenance of adequate amniotic fluid volume is important during the intrapartum period. The apparent protection against cord compression seems to have a direct effect on both maternal and fetal outcome, and our results lend strong support to the technique of amnioinfusion as a prophylactic treatment for oligohydramnios in labor.

In a comparison of the methods of delivery (Tables II and III), it is readily apparent that the infusion group has a statistically significant increase in spontaneous vaginal deliveries and a subsequent decrease in operative deliveries. Operative intervention specifically because of fetal distress is also significantly reduced when one examines the overall rate (including forceps and vacuum) and when cesarean section alone is examined. Prior studies of cesarean section rates have suggested this trend but have not shown a statistical difference because of their smaller sample sizes.^{2, 5} This finding clearly translates to decreased maternal morbidity and a reduction in the number of cesarean deliveries. Of interest is the observation that operative vaginal deliveries because of fetal distress are higher in the study

population (both infused and noninfused patients) than in the general population at Women's Hospital. This is believed to reflect the complication of oligohydramnios in the study population. The observation that the rate did not return to normal in the infusion group suggests that in some patients oligohydramnios is a symptom of a larger problem, not simply corrected by amnioinfusion and restoration of a normal amniotic fluid index.

With regard to fetal outcome, our data show a significant improvement in umbilical artery cord pH in the amnioinfused group. One-minute Apgar scores also were improved, but the 5-minute scores were not statistically different. Our results are similar to those reported in prior studies2,5 and presumably reflect decreased stress in association with the elimination of repetitive variable decelerations.

Of concern in our institution was the possible implication of amnioinfusion with increased rates of amnionitis and endometritis. Strong et al.⁵ reported a 13% increase in infection in his preliminary study of infused patients. This enlarged study failed to show a statistical difference between the infection rates between the control and treatment group, and the differences noted were only 3%. Recent work published by Owen et al.6 has suggested that amnioinfusion may actually provide a protective effect against maternal infection. Our work was unable to confirm this finding.

Of great interest was the shortened length of hospital stay in the amnioinfusion group. While this finding is tied to the decreased rate of operative intervention for fetal distress, its importance is nonetheless diminished. In this era of rising medical costs, decreased hospital time for both mother and infant would seem to provide further incentive for using this technique.

In summary, this study shows that prophylactic amnioinfusion is a safe and simple technique that may be used for the treatment of oligohydramnios in patients in labor. Its benefits include a decrease in the rate of operative intervention for fetal distress, reduced rates of cesarean section, and decreased length of hospital stay. Amnioinfusion has no apparent adverse effects on the fetus or mother and does not appear to increase the rates of maternal infection.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of \$61.00 for domestic, \$88.27 for Canada, and \$84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. Payment must accompany all orders. Contact Mosby-Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

The second stage of labor: Factors influencing duration

Jeanna M. Piper, MD, David R. Bolling, MD, and Edward R. Newton, MD San Antonio. Texas

Prolonged second stage of labor is associated with increased perinatal mortality. Factors influencing second-stage duration are poorly understood. This study was undertaken to characterize those factors. A population of 473 nulliparous women and 491 multiparous women with spontaneous vaginal deliveries were analyzed extensively with history, physical examination (including clinical pelvimetry), labor and delivery data, and neonatal measurements. On the basis of stepwise multiple linear regression, epidural analgesia (p < 0.0001), active-phase duration (p < 0.0001), parity (p < 0.0001), height (p < 0.0004), birth weight (p < 0.0003), and station at complete dilatation (p < 0.027) predicted second-stage duration. The sum of their effect, however, accounted for <25% of the variability in second-stage length (total $R^2 = 0.233$), leaving 75% of the variance unexplained. (AM J OBSTET GYNECOL 1991;165:976-9.)

Key words: Labor, second-stage duration, spontaneous vaginal delivery

Prolonged second stage of labor is associated with increased perinatal morbidity and mortality. The definition of abnormal second-stage length (for example, >2 hours) is arbitrary. Classification of a second stage as normal or prolonged would be much more accurate if individual characteristics could be used to predict its length. Previous studies have associated parity and epidural analgesia with labor duration²⁻⁴; however, strength of correlation was not tested, and no other factors were considered. Some of these studies also included patients whose second stage was artificially shortened by operative delivery. St. 4

To create a model for prediction of second-stage length, a well-characterized population of patients with spontaneous vaginal delivery would be required. This study was undertaken to obtain such a population; to examine the influence of multiple maternal, fetal, and labor characteristics on second-stage duration; and to determine the relative contribution of each factor to the variability in second-stage length. The ultimate goal was to create a mathematic model for prediction of second-stage duration, on the basis of individual characteristics known at the onset of complete cervical dilation.

Material and methods

Women's Hospital and Medical Center Hospital, San Antonio, were enrolled. Patient selection was based on consecutive deliveries, limited by the work schedule of the research personnel. Only women with viable singleton pregnancies were enrolled. Multifetal gestation, intratuerine fetal death, or operative delivery excluded the patient from further analysis. To be enrolled, the women had to have the ability to read and give written consent in English. A population of women with spontaneous vaginal deliveries was created.

During the postpartum hospitalization, three experienced research personnel conducted a chart review, interview, and physical examination of the mother (including clinical pelvimetry) and the neonate. The examiners were uniformly instructed on examination technique by one of the authors (E.R.N.). Interobserver variability was evaluated for clinical pelvimetry, with all observations correlating within 0.5 cm. Extensive data were collected on maternal, neonatal, and labor characteristics (Table I).

Labor management was at the discretion of the attending physician. In general, patients were examined every 1 to 2 hours unless clinically indicated (urge to push, change in fetal heart tracings, etc.). Second-stage duration was defined as the time from diagnosis of complete cervical dilatation to delivery. The active phase of labor was defined as the period from a cervical dilatation of 4 cm to complete dilatation. If the patient was admitted with the cervix dilated >4 cm, active-phase length was measured from admission to complete dilatation. Station was measured as centimeters above or below the ischial spines.

Prepregnancy weight and shoe size were based on patient history. Pregnancy weight gain equaled the difference between weight on admission and prepregnancy weight. Maternal pelvic measurements, made by means of calipers with the patient in lithotomy position, were the transverse outlet diameter (the inside width

Table I. Maternal, neonatal, and labor characteristics

of the anterior ischial rami at the point of their inflection posteriorly and superiorly) and the diagonal from the right ischial ramus to the apex of the subpubic angle. The subpubic angle was calculated with trigonometric formulas.

All neonates were measured by standard techniques. Neonatal chest circumference was measured at the level of the nipples. Shoulder diameter was measured between the most lateral aspects of the acromion. Prior infants' measurements were obtained from the medical records.

· Univariate analysis was performed with the Pearson correlation and the Student t test for continuous data and χ^2 analysis for categoric data, with p < 0.05 considered significant. All significant factors were further examined with one-way analysis of variance and were entered as independent variables in multivariate analysis with stepwise multiple linear regression. Only firstdegree effects were considered.

Results

A total of 1071 women were approached for study inclusion. Of these, 51 refused to participate (4.8%); these women were more likely to be nulligravid (43/51) and to have painful perineal lacerations. The remaining 1020 women were entered into univariate analysis and were used to create the population characteristics. On entry to multiple regression, an additional 56 patients were excluded because of one or more missing data points, leaving a total of 964 women (473 nulliparous, 491 multiparous) for final analysis. Twenty percent of the nulliparous women (102) and 27% of the multiparous women (140) had cervical dilatation >4 cm on admission. The majority of those were 5 to 6 cm, with only 31 nulliparous women (6%) and 56 multiparous women (11%) admitted at >6 cm dilatation. Patients were enrolled from two hospitals (one public, one private) to create a diverse population. The only significant difference between the hospitals in the factors studied was a lower incidence of epidural analgesia at the public hospital (36% vs. 56%).

The population (subclassified as nulliparous, multiparous, and the total group) is characterized further in Table II. Univariate analysis identified parity (p < 0.0001), weight gain (p < 0.015), shoe size (p < 0.032), height (p < 0.001), transverse diameter of pelvic outlet (p < 0.001), subpubic angle (p < 0.037), epidural analgesia (p < 0.0001), activephase length (p < 0.0001), station at complete dilatation (p < 0.008), birth weight (p < 0.007), and head circumference (p < 0.006) as significantly correlated with second-stage duration. Table III illustrates the influence of selected factors on the length of second stage (the significance levels refer to comparison between groups for each factor). Multiple stepwise linear regression was performed with second-stage length as the dependent variable and the significant factors from univariate analysis as the independent variables. Six factors were identified as significant predictors. These factors and their relative contributions to the total variability in second-stage duration are displayed in Fig. 1. The influence of these factors varies between nulliparous and multiparous women and the total group. In all groups, however, the total R^2 was <0.25, with individual R² values ranging from 0.009 to 0.119. Thus the majority of the variability in second-stage length could not be explained by maternal, fetal, or labor characteristics.

Comment

The optimum maximal duration for the second stage of labor has always been controversial. In the nine-

teenth century the controversy stemmed from the preexisting opinion that the second stage should be allowed to continue indefinitely (because of fear of operative delivery) and the experience that maternal and fetal morbidity was proportional to second-stage length. In the midst of this debate, Hamilton, in 1861, created the limit of 2 hours for second-stage duration.

In 1952, Hellman and Prystowsky¹ found that infant mortality rose significantly when second-stage length passed 150 minutes. Their study, as well as Friedman and Knoll's⁶ data published in 1969, found a median

second-stage duration of 50 minutes in nulliparous women and 20 minutes in multiparous women.

The dogma of a 2-hour limit was attacked in 1977 by Cohen, on the basis of his study of 4000 nulliparous women. He found no increase in maternal or neonatal mortality with increased second-stage length as long as the fetal heart tracing remained normal and concluded that it was unwarranted to intervene simply because a time limit had been surpassed. In contrast, Roemer et al. suggested that the second stage should not be allowed to go beyond 45 minutes, on the basis of umbilical cord gas analysis. Katz et al., in 1987, found clinically significant decreases in umbilical arterial pH values as second-stage length increased. They called for a new evaluation of optimal second-stage duration.

In the 1980s, several studies demonstrated that epidural analgesia increased second-stage length.2-4 Kilpatrick and Laros² suggested that the second-stage limit for patients with epidural analgesia be extended to 3 hours. The concept that epidural analgesia might alter the anticipated second-stage length prompted our search for other factors that might improve our ability to predict second-stage duration. Our study attempted to create a model for prediction of second-stage duration on the basis of multiple maternal, neonatal, and labor factors. Our inability to identify the source of the majority of variability in second-stage duration thwarts attempts at mathematic modeling. The source of the remainder of variability must first be identified. Further investigation should be directed toward the powers of labor responsible for fetal descent, including uterine force, contractile pattern, and maternal pushing effort, and to the effects of minor aberrations of fetal position and pelvic architecture. Also, the effect of epidural anesthesia should be further evaluated as to the relative

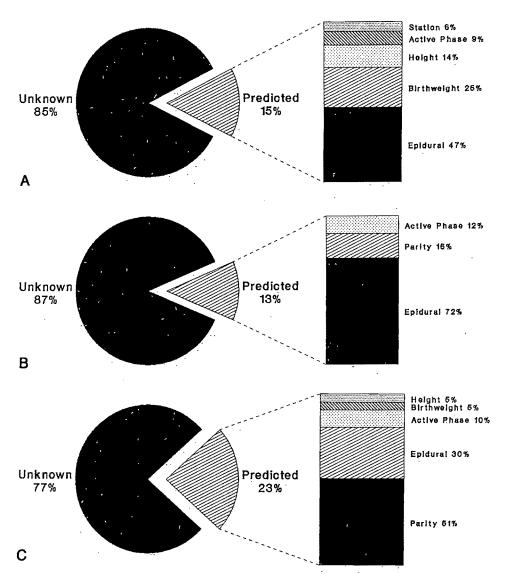

Fig. 1. Sources of variation in second-stage duration and their relative contributions to total variability on basis of multiple linear stepwise regression. A, Nulliparous women; total $R^2 = 0.151$ (n = 473); **B**, multiparous women; total $R^2 = 0.128$ (n = 491); **C**, total group; total $R^2 = 0.233$ (n = 964).

contributions of anesthetic type and density of blockade.

When a predictive model is developed, the anticipated second-stage duration for an individual can be calculated and a pathologic second-stage length can be established, on the basis of maternal and neonatal morbidity and mortality. Thus the timing of intervention for a prolonged second stage can be tailored to decrease operative intervention and improve maternal and neonatal outcome.

A prospective study of two dosing regimens of oxytocin for the induction of labor in patients with unfavorable cervices

Andrew J. Satin, Capt, USAF, MC, Gary D.V. Hankins, Lt Col, USAF, MC, and Edward R. Yeomans, Lt Col, USAF, MC

Lackland Air Force Base, Texas

The ideal regimen for induction of labor with oxytocin with respect to the magnitude and frequency of dosage changes has not been defined. In spite of few data regarding labor induction with an unfavorable cervix, the initial dose recommended by the American College of Obstetricians and Gynecologists is lower than that of other commonly used protocols. Eighty patients with unfavorable cervices and unruptured membranes, without evidence of labor, were randomized to one of two protocols and met criteria for data analysis. Patients in both protocols were given an initial dose of oxytocin of 2 mU/min. Patients in protocol A (n=32) then received incremental increases of oxytocin of 1 mU/min at 30-minute intervals, while those in protocol B (n=48) received incremental increases of 2 mU/min at 15-minute intervals. Induction failures were higher among patients on protocol A (31% vs 8%, p<0.05). Patients on protocol B had shorter times to delivery (mean = 10 hours 57 minutes vs 8 hours 3 minutes; p<0.05). The number of operative deliveries were similar regardless of protocol. There were no significant differences (p=NS) among groups and protocols in maternal and fetal complications, cesarean section rate, and uterine hyperstimulation. In this population a more aggressive protocol may lead to fewer induction failures and shorter induction-to-delivery intervals. (Am J Obstet Gynecol. 1991;165:980-4.)

Key words: Oxytocin, induction of labor, unfavorable cervix

The induction of labor is defined as the initiation of uterine contractions before the spontaneous onset of labor by medical or surgical means, or both, for the purpose of accomplishing delivery.1 Dilute intravenous oxytocin infusion remains the only agent approved by the Food and Drug Administration for induction at the present time. Numerous induction protocols exist involving different initiation doses, rates of increase, and time intervals between increases. An infusion beginning with 0.5 to 1.0 mU/min with incremental increases of 1 mU/min at 30- to 60-minute intervals is currently recommended by the American College of Obstetricians and Gynecologists. The recommendation derives its basis principally from data reported by Seitchik and Castillo² obtained from patients who had presented in labor and received oxytocin for augmentation of labor. Hauth et al.3 subsequently demonstrated that significantly less oxytocin and less uterine activity are required for successful augmentation of labor versus induction of labor. Accordingly, information regarding the amount of oxytocin required and uterine contraction forces obtained during labor augmentation may have little or no relevance as regards labor induction.

Delivery is often indicated in women with unfavorable cervices, especially in prolonged pregnancies, which constitute 7% to 12% of all gestations. A Ecommendations for induction management have been based on retrospective, uncontrolled populations or patients undergoing augmentation rather than induction of labor. The purpose of our study was to compare the efficacy and safety of two commonly used induction regimens in a prospective, controlled manner in patients not in labor and with unfavorable cervices.

Material and methods

The study population consisted of women admitted to the labor and delivery suite for the induction of labor. The majority (94%) of women undergoing induction had postterm pregnancies (≥42 weeks' estimated gestational age). Women were examined before enrollment and were included only if the results of cervical examination were unfavorable (dilatation ≤2 cm and a Bishop score ≤6) and there was no evidence of regular uterine activity or evidence of rupture of fetal membranes. Approval for this study was granted by the institutional review board. After informed consent was obtained from each patient, an

unmarked, sealed envelope was opened, which assigned the patient to one of the protocols (Table I). Women presenting for induction of labor were excluded from the study if they had a malpresentation, placenta previa, active herpes infection, or hypertensive disease necessitating magnesium sulfate treatment or if a deviation from dosing protocol had occurred.

Regardless of protocol, patients receiving oxytocin were monitored in a similar fashion.6 A baseline fetal heart rate tracing was obtained before initiation of oxytocin. Standard recording of vital signs included continuous fetal heart rate monitoring and uterine contractions and serial 15-minute recording of maternal blood pressure, pulse, and fetal heart tones. Contraction intensity, duration, and frequency and maternal fluid intake and output also were recorded. Oxytocin dosages were increased until an adequate labor pattern was achieved. An adequate labor pattern was defined as labor resulting in cervical change. Amniotomy was performed only after cervical change occurred and the patient was diagnosed as having progression beyond latent-phase labor. After rupture of membranes, a fetal scalp electrode and intrauterine pressure catheter were placed. In the absence of cervical change oxytocin was increased per each particular protocol until >200 montevideo units per 10 minutes was achieved.7 At 8 to 10 hours after the start of induction, if cervical dilatation or spontaneous rupture of membranes had not occurred and there was no evidence of fetal distress or maternal illness, the induction was considered failed.

Age, race, parity, estimated gestational age, height, weight, indication for induction, Bishop score, cervical examination result, and medical history were recorded for all patients. Other potential confounding variables such as birth weight and method of anesthesia also were compared. Duration of the first and second stages of labor were recorded. The maximum doses of oxytocin were noted.

Maternal outcome parameters tracked included the frequency of operative deliveries, chorioamnionitis, postpartum endometritis, and postpartum hemorrhage. Neonatal outcome as reflected by Apgar scores, umbilical cord gas values, pH, infection rate, and hospital stay also were compared.

Statistical analysis was performed with the Mann-Whitney U test, χ^2 contingency tables, and Fisher's exact test as indicated.

Results

The study included 80 women, 32 on protocol A and 48 on protocol B. An additional eight patients were excluded from protocol A and two from protocol B because hypertensive disease necessitating magnesium sulfate prophylaxis. Six patients were excluded from protocol A because of a deviation in dosing protocol.

Table I. Induction protocols in 80 women with unfavorable cervices

Protocol A included 31 postdate pregnancies and one case of gestational diabetes; 15 of these women were nulliparous and 17 were parous. Protocol B included 44 women with postdate pregnancies, one with chronic hypertension, two with gestational diabetes, and one with suspected macrosomia. Protocol B consisted of 22 nulliparous and 26 parous women.

Comparisons of maternal age, parity, estimated gestational age, height, and weight were similar between protocols (Table II). There were no significant differences in the use of epidural anesthetics in labor between the two protocols (25% in protocol A and 27% in protocol B).

There were 10 (31%) induction failures with protocol A compared with 4 (8%) with protocol B (p < 0.05). Times from onset of induction to completion of the first and second stages of labor are summarized in Table III. Patients on protocol B had a significantly (p < 0.05) shorter time to delivery. The mean induction-to-delivery time in nulliparous women on protocol A was 15 hours 18 minutes versus 9 hours 16 minutes for those on protocol B (p < 0.05). There was also a significant difference in parous women (10 hours 54 minutes in group A vs 8 hours 2 minutes in group B; p < 0.05).

The number of times the oxytocin had to be stopped or decreased because of hyperstimulation and fetal heart rate abnormalities is depicted in Table IV. The maximum dose of oxytocin used to achieve adequate labor was significantly higher in protocol B than pro-

tocol A (25.5 \pm 9 vs 14.4 \pm 7 mU/min; p < 0.05). There were no emergent deliveries in either group or any infants with evidence of umbilical arterial or metabolic acidemia.

Maternal complications, specifically the number of operative midpelvic and abdominal deliveries, chorioamnionitis, postpartum endometritis, and postpartum hemorrhage, were not significantly different between protocols (Table V). Infant demographics were also similar for birth weight, low Apgar scores, ominous cord gases, and neonatal infections (Table VI).

Comment

The optimal regimen of oxytocin for induction of labor, particularly in patients with unfavorable cervices, is unknown. One of the most frequent indications for induction of labor is a gestation of ≥42 weeks. The likelihood of achieving vaginal delivery can be predicted by the Bishop score. With a score of ≥ 9 , >50%were delivered within 5 days without intervention.8 Hayashi considered a pelvic score >6 to equate with successful induction and vaginal delivery.1 The rate of successful inductions in patients with scores <6 goes down significantly. The incidence of cesarean delivery in patients who are postdates and have unfavorable cervices varies from 6% to 51%.9-12 In large part this is accounted for by whether the patient with an unfavorable cervix is allowed sequential inductions or is committed to delivery the same day by amniotomy. Accordingly, we have previously reported a system of trial

inductions of labor in postdate gestations with intravenous oxytocin beginning at 2 mU/min and increasing by 2 mU/min every 15 minutes until an adequate labor pattern is achieved.12

Recently, it was recommended that lower doses of oxytocin and longer intervals between dose increases be used for induction of labor. 1, 2, 13, 14 The initial study of Seitchik et al.15 involved only women at ≥38 weeks' gestation who had already entered labor and required oxytocin for augmentation of labor. They reported a higher incidence of delay in time until the second stage in patients receiving higher doses of oxytocin with shorter intervals between dosing increases in association more transient curtailments of infusion out of concern for hyperstimulation and fetal distress. In this retrospective review they concluded that concerns for discontinuing the medication were rarely of pathophysiologic significance. Seitchik et al.15 subsequently demonstrated that approximately 40 minutes is required for any particular dose of oxytocin to reach steady state. Hauth et al., susing an induction regimen with 1 to 2 mU/min increases at intervals of \geq 15 minutes, reported that 29% of women requiring oxytocin induction received >20 mU/min, whereas only 14% of women undergoing augmentation required >10 mU/min,3 thus suggesting that the optimal regimen of oxytocin for augmentation versus induction may be quite different.

Some recommend increasing oxytocin at 15-minute intervals on the basis of its short plasma half-life.16, 17 Foster et al.¹⁸ retrospectively compared 15-minute versus 30-minute dosing intervals in patients with mean cervical dilatation >4 cm undergoing augmentation. These authors reported no significant differences in time to delivery, cesarean section rates, or complications between regimens. Blakemore et al. 14 contrasted hourly versus 15-minute dosing intervals. Their study population included patients with various initial examinations. Although the average induction-to-delivery times were 1 hour 40 minutes shorter in the 15-minute group, the authors assumed a normal distribution of data and concluded this was not a significant difference.

Parous	0 .	2	0	0

p = NS.

Our data suggest advantages and disadvantages for each protocol. Protocol A required a lower maximum dose of oxytocin to achieve vaginal delivery in those patients with progression beyond the latent phase. However, we saw no adverse consequences such as antidiuresis, postpartum hemorrhage, or uterine rupture in patients receiving on average of 25 versus 14 mU/min of oxytocin. Patients in protocol A also required less intervention because of hyperstimulation. However, none of these episodes regardless of protocol necessitated emergent delivery, and none of these infants were born with a metabolic acidosis. Treatment consisted of a combination of supplemental oxygen, lateral tilt of the patient, or a transient discontinuation of infusion.

More patients had progression beyond the latent phase in an 8- to 10-hour period on protocol B as evidenced by fewer failed inductions. Time to delivery also was shorter for patients on protocol B (with the Mann-Whitney U test and not assuming a normal distribution of data). In the clinical setting of postdate pregnancy with an unfavorable cervix, a willingness to offer sequential inductions and a more aggressive protocol may optimize time to delivery without increasing the number of operative deliveries. The shorter time in labor and lower incidence of failed inductions will lead to an overall decrease in hospital stay and cost. Differences in our results compared with those of previous investigations may merely reflect differences in study populations. Our results imply that the application of data and recommendations derived from augmentation of labor in patients with favorable cervices to women with unfavorable cervices undergoing induction may not be valid. Although the higher incidence of hypertensive disease on protocol A was not significant, this combined with protocol dosing errors may have provided a source of exclusion bias. Nevertheless, because major complication rates are similar, the various regimens remain acceptable and should be available at the discretion of the individual clinician.

Do catechol estrogens participate in the initiation of labor?

Anjan Biswas, PhD, Anjan Chaudhury, MD, Sati C. Chattoraj, PhD, and Sidney L. Dale, PhD

Boston, Massachusetts

To assess the role of catechol estrogens in the initiation of labor, we compared the levels in amniotic fluid during the second and third trimesters and from women undergoing cesarean section at term not in labor and those with spontaneous labor at term. Catechol estrogen concentrations in amniotic fluid increased significantly with the progress of pregnancy. Further, concentrations (mean \pm SE) were significantly higher in spontaneous labor at term (468.6 \pm 29.5 pg/ml) compared with those obtained during cesarean section (242.6 \pm 22.3 pg/ml) at term not in labor. We suggest that catechol estrogens, through their stimulating effects on prostaglandin synthesis, participate in the initiation of labor. (AM J OBSTET GYNECOL 1991;165:984-7.)

Key words: Catechol estrogens, amniotic fluid, labor, gestational age, prostaglandin

The mechanism of the onset of labor in humans still remains incompletely understood. As opposed to ruminants, human parturition is not preceded by dramatic changes in the concentration of progesterone or estrogens in maternal circulation or changes in cortisol levels in the fetal circulation. In spite of the differences in the biochemical events occurring before labor among species, the central role of prostaglandins in the normal onset and progression of labor in all mammalian species studied so far has become evident in recent years.

Whereas the factors initiating and regulating prostaglandin synthesis in the fetal membrane and the uterine wall remain to be elucidated, catechol estrogens, major metabolites of estrone and estradiol in both laboratory animals and humans, 3,4 can be a significant factor in this regard. Recent studies have shown that catechol estrogens increase the production of prostaglandins even more than does the parent compound in rat

and human uterus,5 intrauterine tissues at parturition,6 and rabbit blastocysts and endometrium.7 As potent competitive inhibitors of catechol-O-methyltransferase, catechol estrogens potentiate the lipolytic effect of epinephrine in releasing arachidonic acid from phospholipids.8 It is interesting to note that catechol-O-methyltransferase, which is the enzyme of prime importance in the metabolism of catechol estrogens and the catecholamines, has been found to be very high in human decidua vera tissue during pregnancy, reaching maximum levels at term.9 The conversion of estrogens to catechol estrogens in human uterus10 and placenta11 and in a host of other tissues including the fetal brain and pituitary⁸ make catechol estrogens an important factor to be considered in the mechanism of parturition. We have previously shown that umbilical venous and arterial levels of catechol estrogens are significantly higher at vaginal delivery than at abdominal delivery, without any significant difference in the maternal peripheral plasma content between the two modes of delivery.12 We have also reported recently that urinary catechol estrogens excretion in rats increases during pregnancy, reaching maximum levels before labor.18

In view of these considerations, our investigation was undertaken to evaluate further the status of catechol estrogens in amniotic fluid during pregnancy and at different modes of delivery. Results show that levels of catechol estrogens increase with the progress of preg-

nancy and are significantly higher at vaginal delivery in comparison with those obtained at abdominal delivery not in labor.

Material and methods

Fifty-four healthy women who gave informed consent (21 to 36 years old) were included in our study, which was approved by the institutional review board. Amniocentesis was performed as a part of clinical care. Amniotic fluid was collected during the second trimester $(17.1 \pm 1.2 \text{ weeks})$ of pregnancy for fetal karyotyping (n = 7) and from third-trimester patients $(36.1 \pm 0.9 \text{ weeks})$ for determination of fetal lung maturity (n = 9). Samples of amniotic fluid (38.8 ± 1.5) weeks) were obtained during cesarean section (not in labor) by needle aspiration through the intact membrane after the uterine wall was opened (n = 18) and from women in active labor (39.9 \pm 1.3 weeks) from a pressure catheter introduced at the time of amniotomy (n = 20). Patients in the study group were free of medical and obstetric complications. Oxytocin, narcotics, anesthetic agents, and antibiotics were not used before delivery. Continuous epidural analgesia was provided for both modes of delivery. The fluid was collected in sterile containers containing 0.5 ml of 5% aqueous ascorbic acid to ensure the stability of catechol estrogens and stored at -20° C until analyzed.

Radioactive and inert 2-hydroxyestrone was synthesized, purified, and stored as described by us.4 Organic solvents were purchased (glass distilled) from Burdick and Jackson Labs, Inc. (Muskegon, Mich.). The phosphate-saline solution buffer (0.1 mol/L, pH 7.2; 0.9% sodium chloride, 0.1% sodium azide, and 0.1% globulin fraction II) used in the radioimmunoassay contained 0.05% ascorbic acid for the protection of the catechol estrogens.4

Dextran-coated charcoal was prepared by adding 0.5 gm dextran T-70 (Pharmacia Fine Chemicals, Piscataway, N.J.) to 5 gm Norit A (Fisher Scientific Company, Pittsburgh) in 40 ml buffer and was diluted to 10 mg charcoal/0.2 ml before use. Radioactivity was counted in 10 ml Liquiscint (National Diagnostics, Somerville, N.J.). Radioimmunoassay was performed as previously described by us4, 12 with minor changes. Samples of 1 ml aliquots were extracted with 10 ml methylene chloride that was washed with 2 ml bicarbonate buffer and 10% acetic acid. The organic extract was evaporated to dryness under a stream of nitrogen. Catechol estrogen was then quantitated with a 5% aliquot of the extract, in duplicate, by radioimmunoassay. Water blanks and control samples were also included in each assay. Blank values were subtracted before final computation. Recovery of added radioactive 2-hydroxyestrone was $72.3\% \pm 7.3\%$ (mean \pm SD). Water blanks were 3.4 ± 1.9 pg (mean \pm SD). Sensitivity, defined as the mean of the blank value plus 2 SD, is 7.2 pg per tube.

Table I. Parallelism tests for catechol estrogen analysis in amniotic fluid (picograms per milliliter)*

Dilution	Observed value	Expected value (% difference)
0	375	375
1:2	200	188 (+6)
1:3	108	125 (-13.6)

^{*}Data yielded a correlation coefficient of r = 0.99.

The specificity of measurements of catechol estrogens has been reported in our previous publications.4.12 For this study samples were further subjected to parallelism tests by assaying undiluted and diluted samples (Table I). The correlation coefficient (0.99) of parallelism tests indicates that the relative rankings of the two data sets involved are nearly perfect. The intraassay and interassay coefficients of variation were 5.8% and 6.7%, respectively.

In our study no chromatographic separation was performed before radioimmunoassay; thus the results include 2-hydroxyestrone and 2-hydroxyestradiol because both cross react 100% with the antisera.4 Statistical comparison of the mean level of catechol estrogens across the four study groups was made through analysis of variance. Subsequent pairwise comparisons of groups were made through the Tukey multiple comparison procedure.

Results

Levels of catechol estrogens in amniotic fluid during pregnancy and in amniotic fluid obtained during both modes of delivery are depicted in Fig. 1. The gestational age between two modes of delivery was not statistically different. Levels of catechol estrogens differ significantly (p < 0.001) across the four study groups. Multiple comparisons show that levels of catechol estrogens (mean \pm SE) increase significantly (p < 0.001) in the third trimester (208.5 \pm 22.4 pg/ml) compared with the levels observed in the second trimester (65.0 \pm 9.5 pg/ml). A sharp rise in the level of catechol estrogens was observed (p < 0.001 pg/ml) during spontaneous labor at term (468.6 \pm 29.5 pg/ml) compared with that of the third trimester and at cesarean section $(242.6 \pm 22.3 \text{ pg/ml})$. There was no significant difference in levels observed between the third trimester and cesarean section at term.

Comment

Concentrations of catechol estrogens in amniotic fluid increase significantly with the progress of pregnancy, reaching maximum at term. There is no significant difference between the levels in the third trimester and those obtained at cesarean section at term. How-

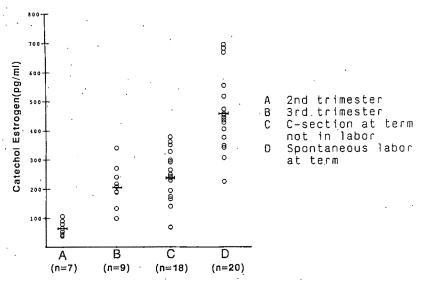

Fig. 1. Catechol estrogen concentrations (picograms per milliliter) during pregnancy and at different modes of delivery. Mean indicated by *horizontal bar. A* versus B, p < 0.001; B versus D, p < 0.001; B versus D, p < 0.001.

ever, a dramatic increase in concentration of catechol estrogens is observed in amniotic fluid collected at vaginal delivery (Fig. 1). Our data corroborate our previous findings of a significantly elevated concentration of catechol estrogens in cord blood at vaginal delivery.12 Significantly higher levels in both cord blood and amniotic fluid at vaginal delivery in comparison with those obtained at abdominal delivery would suggest that before or at the onset of labor there is an increase in production of catechol estrogens. Furthermore, since there is no significant difference in maternal peripheral plasma levels of catechol estrogens between the two modes of delivery,12 the increased production is perhaps localized to the fetoplacental complex, including fetal membranes. We have previously suggested that because of the high metabolic clearance rate, catechol estrogens in the peripheral circulation are not able to play a significant role in the reproductive processes.14 If there is any intrinsic role for catechol estrogens, then it is through their formation in the tissues in which they act.14, 15 Indeed, the absence of perceptible changes in progesterone and estrogen concentrations in the maternal peripheral plasma, either at term or in association with preterm labor,16,17 prompted investigators to study the formation of steroids within the intrauterine tissues and consequent paracrine regulation of prostaglandin production. 18, 19 Fetal membranes and decidua are capable of producing estrone and estradiol, and the activity of the enzyme estrone sulfatase in decidua and chorion increases substantially with the onset of labor.20 Thus the supply of unconjugated estrone may result in increased formation of catechol estrogens in the fetal membranes. Alternatively, the increased accumulation of catechol estrogens in amniotic fluid may be due to fetal urinary excretion. It is possible that as the fetus matures there is increased excretion of catechol estrogens into the amniotic fluid, reaching a maximum before the onset of labor. Catechol estrogens in turn, by transmembrane diffusion, directly or indirectly augment the synthesis of prostaglandin in the fetomaternal lining, leading to the initiation of labor and delivery. The report on the existence in fetal urine of a stimulatory substance of small molecular weight for prostaglandin synthesis²¹ strengthens such a proposition.

Catechol estrogens may also indirectly stimulate prostaglandin formation. Catecholamines are present in amniotic fluid in increasing concentration during late pregnancy.22 They may stimulate adenylate cyclase and influence prostaglandin production through β-adrenergic receptors present in the amnion tissue.23 Because catechol estrogens are potent competitive inhibitors of catechol-O-methyltransferase, they can protect catecholamines from inactivation, thereby potentiating and prolonging the action of these substances. The existence of protein-stimulating and protein-inhibitory substances in amniotic fluid for prostaglandin synthesis has been reported.18 Wilson et al.24 have recently described the isolation and purification of a protein from amniotic fluid that inhibits release of arachidonic acid from human decidual cells. The functional relationship of catechol estrogens with this and other inhibitory substances in amniotic fluid is not known.

We thank Dr. David Acker for his continued support and interest, Dr. Tim Haren for statistical analysis, Dr. Aleksander Gajewski for his technical assistance, and Ms. Dallas Slawter for her assistance with manuscript preparation.

The effect of fetal movement counting on maternal attachment to fetus

Magdy S. Mikhail, MD, Margaret C. Freda, EdD, RN, Ruth B. Merkatz, PhD, RN, Regina Polizzotto, MS, CNM, Evelyn Mazloom, MPH, CNM, and Irwin R. Merkatz, MD *Bronx, New York*

The effect of fetal movement counting on maternal attachment to fetus was investigated in 213 women with uncomplicated singleton pregnancies at 28 to 32 weeks' gestation. Women were randomized into those who counted fetal movements using the Sadovsky (n=63) or Cardiff (n=62) charts and controls (n=88). After 1 month of fetal movement counting, the Cranley 24-item scale with five subscales was used as a measure of maternal-fetal attachment. Univariate analysis revealed a statistically significant increase in total attachment scores and in each of the five attachment subscales among women who counted fetal movements (p<0.001). Tukey's studentized range test confirmed significant differences between each of the Sadovsky and Cardiff groups compared with controls (p<0.05). Our study suggests that fetal movement counting may enhance the maternal-fetal attachment process. (AM J OBSTET GYNECOL 1991;165:988-91.)

Key words: Maternal-fetal attachment, fetal movement counting

Maternal attachment to the fetus has been defined as the mother's affiliation and interaction with her unborn fetus. It develops during pregnancy as a result of dynamic psychologic and physiologic events and may be an important prerequisite to successful mother-infant adaptation. ^{2, 3}

Factors that influence the maternal-fetal attachment process are still being explored. Ultrasonographic examination, by providing a visual representation of the fetus in the early weeks of pregnancy, was shown in one study to promote maternal feelings of attachment.4 Quickening has also been demonstrated to be positively related to both prenatal and postnatal attachment behaviors. 5.6 With the onset of fetal movement, the nesting process appears to begin.7 Thus fetal movement may be a developmental variable influencing maternalfetal attachment. Hence, it has been suggested that helping mothers become more attuned to the occurrence of fetal movement may facilitate feelings of attachment.⁵ The purpose of this study was to examine the effect of fetal movement counting on maternal-fetal attachment. The specific research questions were: (1) What is the effect of fetal movement counting during the third trimester of pregnancy on maternal-fetal attachment? (2) Is there a difference between two methods of fetal movement counting (Sadovsky and Cardiff) on maternal-fetal attachment scores?

Material and methods

Two hundred thirteen pregnant women attending a prenatal clinic at the Bronx Municipal Hospital Center, Bronx, New York, were recruited and gave informed consent. The protocol was approved by the institutional review committee. All subjects had normal, uncomplicated singleton pregnancies. The gestational age ranged between 28 and 32 weeks of pregnancy. In an effort to use the two most common fetal movement counting methods, both the Sadovsky chart⁸ (counting three times a day after meals) and the Cardiff chart9 (counting the first 10 movements each morning) were used. Women were allocated to groups by a computergenerated random list. Women were randomized into those who counted fetal movements using the Sadovsky (n = 63) or Cardiff (n = 62) charts and controls (n = 88). Compliance was determined by number of days counted. Women in the control group did not count their fetal movements. Instructions were read to each participant from a printed script to ensure uniformity of counseling. All subjects completed demographic questionnaires. After 1 month of fetal movement counting, the Cranley 24-item scale with five subscales was used as a measure of maternal-fetal attachment. All women in the three groups completed the Cranley scale.

The Cranley maternal-fetal attachment scale consists of 24 Likert-type items describing baby-related thoughts and actions of expectant mothers. The Likert-type items comprised five responses to each question.

Subjects were asked to circle one answer only. The responses are arranged on a five-point response set as follows: most of the time, frequently, sometimes, rarely, never. The scale is scored by assigning values to the responses (most of the time is 5, never is 1) and summing the item values. One item, "I feel that my body is ugly," has reversed scoring. The subscales are designed to measure (1) differentiation of self from fetus, (2) interaction with the fetus, (3) attributing of characteristics to the fetus, (4) giving of self, and (5) maternal role-taking. Internal consistency reliability (Cronbach's a) for the entire scale has been reported by Cranley¹ to be 0.85 and by Mercer et al.¹⁰ to be 0.80. All of the subscales were reported1 to be positively associated with the total scale (r = 0.61 to 0.83).

Results

Most of the women were Hispanic (48.1%), unmarried (60.8%), and unemployed (77.1%). The mean age was 24, with a range of 17 to 37 years. The mean years of education was 11.09. All subjects came from the Bronx borough in New York City, and the majority were multiparous (53.3%). Seventy-eight percent of those who counted completed the fetal movement graph on a daily basis. There was no statistically significant difference observed in compliance among women using the Sadovsky versus Cardiff

Table I presents the demographic characteristics of the women by randomized group. At least 65% of the women in each group had between 9 and 12 years of education.

Univariate analysis compared the total and subscale

maternal-fetal attachment scores for women who counted fetal movement versus women who did not count (Table II). There was a statistically significant increase in total attachment scores and an increase in each of the five attachment subscales among women who counted their fetal movements (p < 0.0001). Both total and subscale maternal-fetal attachment scores were lower in the control group when compared with groups A and B.

Tukey's studentized range test confirmed significant differences between each of the Sadovsky and Cardiff groups compared with controls. There were significant differences (p < 0.05) in total and in each of the subscale attachment scores between group A versus group C and between group B versus group C. There were no significant differences in attachment scores between groups A and B.

Linear regression modeling was performed to test any interaction effects of maternal demographic variables on attachment scores. None of the variables presented in Table I was statistically significant. However, there was a trend correlating lower educational levels and nulliparity with decreased attachment scores. A larger sample size is needed to determine the true effects of these demographic variables on maternal-fetal attachment.

Comment

This study was conducted to examine the effect of fetal movement counting on maternal-fetal attachment. The authors did not think that different methods of fetal movement counting would have different effects on attachment scores, but rather the process of count-

ing, regardless of the method used, may enhance maternal-fetal attachment. To demonstrate that it is the process rather than the method, we used two different fetal movement counting techniques. Our study demonstrates that women who counted their fetal movements had higher attachment scores compared with controls. This suggests that fetal movement counting enhances maternal-fetal attachment. It is possible that through movement the fetus may be engaging the mother in a set of behaviors that propel her feelings of affiliation and interaction with the fetus.

Originating in the psychologic work of Deutsch¹¹ and Bibring et al.12 the process of maternal-fetal attachment has been described as fundamental in preparing the mother for the real infant and fortifying her with the emotional energy she will need in the mothering role. Benedek¹³ supported a model of symbiosis between mother and fetus with each member contributing to the emergence of motherliness. In delineating the developmental stages of the pregnancy experience, Caplan¹⁴ theorized that the event of quickening assists the mother to begin conceptualizing the fetus as a separate being. Leifer15 identified several maternal behaviors indicative of maternal-fetal interaction, including talking to the fetus, offering the fetus food, and calling the fetus by a name. Brazelton¹⁶ suggested that the communicative relationship between mother and fetus in utero affects the rhythm of the mother-infant dyad after birth. He considered the baby to be an active participant in the attachment process and demonstrated the reciprocal nature of maternal-infant behavior. It now appears that this reciprocity begins before birth. With awareness of fetal movement, the psychologic process of attaching to the fetus seems to be hastened.

It is conceivable that enhancing the maternal-fetal attachment process may in turn improve patient compliance with prenatal health care, facilitate maternal adjustment during pregnancy, and have positive longterm effects on mother-child attachment. A child's secure attachment to the mother has been shown to be positively correlated with the child's exploration ability, problem-solving capability, sociability, and control in the preschool years.17 In that the attachment process is conceptualized as a complex life span phenomenon, additional studies are needed to determine whether promoting maternal-fetal attachment through techniques such as fetal movement counting has any longterm favorable consequences on mother-child relationship. The results of our study should be regarded as tentative. Caution is suggested before generalized recommendations involving regimental fetal movement counting for the purpose of enhancing the maternalfetal attachment process.

We thank Sheila Loeb, MS, CNM, and Anita Shore, CNM, for their assistance with subject recruitment.

A randomized, double-blind trial of prostaglandin E₂ gel for cervical ripening and meta-analysis

John Owen, MD, Carey L. Winkler, MD, Bruce A. Harris, Jr., MD, John C. Hauth, MD, and Mary C. Smith, PhD

Birmingham, Alabama

The ability of prostaglandin E_2 to prepare the unripe cervix before an indicated labor induction is controversial. We therefore tested 100 pregnant women in a randomized, double-blind trial with intracervical prostaglandin E_2 gel, 0.5 mg. The 53 women who received the placebo gel had an outcome similar to that of the 47 women who received the prostaglandin E_2 gel. The mean change in cervical score, mean application-to-delivery interval, incidence of uncomplicated spontaneous labor, incidence of cesarean delivery for a failed induction, and the overall cesarean section rate were not significantly different for the two groups. A meta-analysis, incorporating 18 studies of 1811 patients who received a single application of at least 5 mg prostaglandin E_2 gel intravaginally or 0.5 mg intracervically, demonstrated no significant decrease in the overall cesarean delivery rate (p=0.85). We conclude that the use of single-dose intracervical prostaglandin E_2 gel for cervical ripening has little effect on labor induction. Moreover, the use of single-dose intracervical or intravaginal prostaglandin E_2 gel does not alter the incidence of cesarean delivery, even when large numbers of patients are analyzed by combining the results of similar reports. (AM J OBSTET GYNECOL 1991;165:991-6.)

Key words: Prostaglandin E2, cervical ripening, metaanalysis

The dilatation, effacement, and other components of the cervical score have a significant effect on the success of an indicated induction of labor. Recently, prostaglandin E₂ (PGE₂) gel has been shown to increase the cervical score and facilitate an oxytocin labor in-

From the Division of Maternal and Fetal Medicine, Department of Obstetrics and Gynecology, and the Center for Nursing Research, University of Alabama at Birmingham.

Reprint requests: John Owen, MD, Department of Obstetrics and Gynecology, University Station, Birmingham, AL 35294. 6/6/31431 duction.²⁻⁷ Whether the use of PGE₂ gel actually improves the cesarean delivery rate is unclear. The purpose of this study was to evaluate the efficacy of a single dose of 0.5 mg of PGE₂ gel for cervical priming before an indicated induction of labor. Furthermore, we have used the technique of meta-analysis to evaluate the role of PGE₂ gel in obstetrics by assessing its influence on the cesarean delivery rate.

Material and methods

Randomized, double-blind study. From March 1, 1987, to Nov. 30, 1989, we obtained informed consent to test PGE₂ gel as a cervical ripening agent. The study

was approved by the institutional review board at the University of Alabama at Birmingham. Candidates were recruited from among patients who were receiving obstetric care in the local health departments or in the University of Alabama at Birmingham obstetric complications clinic. Women with a maternal or fetal indication for labor induction,⁸ a Bishop score ≤4, no evidence of intractable fetal distress, and intact membranes were eligible for the study. Women with known hypersensitivity to prostaglandins, history of asthma or glaucoma, or vaginal bleeding were excluded. Patients who had failure of a previous attempt at labor induction, who had a contraindication to labor induction,⁸ or who were having spontaneous contractions (six or more per hour) also were excluded.

All study patients were admitted to the labor suite where electronic fetal monitoring and tocodynamometry were initiated and venous access was obtained. After a digital examination was performed to determine the preapplication Bishop score,8 a speculum was used to visualize the cervix, and 1 ml of gel was inserted into the cervical canal with a small, flexible catheter. Each patient remained recumbent for at least 1 hour while fetal heart rate and uterine activity monitoring were continued. Thereafter, patients were permitted to ambulate for brief periods, but external monitoring was otherwise continued throughout the gel latent period. After 12 hours a repeat cervical examination was performed to determine the postapplication Bishop score. If contractions sufficient to cause progressive cervical change ensued, labor was diagnosed and the postgel cervical scoring was omitted. Similarly, if the fetal heart rate tracing became nonreassuring, necessitating placement of internal monitoring devices, or if another significant obstetric intervention occurred during the latent period, a repeat cervical score also was not determined. Otherwise, induction of labor was then undertaken with a dilute oxytocin infusion, beginning at 1 mU/min, with escalating doses at intervals of 15 to 30 minutes until a satisfactory uterine contraction pattern (three in 10 minutes) was established. Amniotomy and placement of internal monitoring devices were generally postponed until progressive cervical change was documented. Once begun, the oxytocin infusion was generally continued for a minimum of 12 hours before a failed induction was diagnosed and a cesarean delivery performed. However, serial inductions were permitted, and the decision to extend the induction to subsequent days was made by the attending faculty. In these cases the oxytocin induction was suspended overnight. The diagnosis of a failed induction of labor and the decision to perform a cesarean delivery for this indication were made by the attending faculty.

The active gel was prepared in the hospital pharmacy by slowly melting a 20 mg PGE_2 suppository (Upjohn) and suspending it in hydroxyethylcellulose gel (K-Y jelly, Johnson & Johnson), yielding a final PGE_2 concentration of 0.5 mg/ml.⁹ The placebo gel consisted only of hydroxyethylcellulose, and 1 ml of each mixture was placed in a syringe and catheter. Syringes containing the active gel were stored at -4° C until use, at which time the samples were gradually warmed to room temperature, brought to the labor suite, and administered. Active products were reformulated as necessary with a maximum shelf-life of 35 days. Randomization was performed in the pharmacy and directed by the contents of the next sealed envelope.

Data were analyzed using χ^2 , Fisher's exact test, and the Student t test where appropriate. A p value ≤ 0.05 defined statistical significance.

Meta-analysis. A search of the English language literature from 1966 through 1989 was performed to identify reports of PGE₂ applied locally for cervical ripening before induction of labor. Minimum inclusion criteria were use of a randomized, controlled (either a placebo or no-treatment group) study design, a living fetus, an unfavorable cervical score, an intact amnion, a single local application of PGE₂ gel into the vagina or cervical canal, a minimum dose of 0.5 mg intracervical or 5 mg intravaginal, subsequent labor induction with a continuous dilute oxytocin infusion, and an interpretable cesarean delivery rate. Failure to use a doubleblind design or even an unblinded application of placebo gel did not prevent inclusion in this analysis as long as an untreated, randomized control group was included. Control groups that were actually treated by immediate amniotomy or with a continuous oxytocin infusion were excluded. All reports were identified by using a computerized MEDLINE search (performed by two independent, experienced researchers), a bibliography review of identified articles, the proceedings of the Society of Gynecologic Investigation, 1984 to 1990, the proceedings of the Society of Perinatal Obstetricians, 1984 to 1990, and a query to the Oxford Database of Perinatal Trials.¹⁰ Reports whose titles clearly implied that the PGE2 was being used for an induction of labor (as opposed to cervical ripening) or that a route of administration other than locally applied PGE₂ gel was used were not examined. All other reports were considered for potential inclusion, and either the abstract or the entire article was examined with reference to the inclusion criteria. If a particular report could not be excluded solely on the basis of its abstract (e.g., lower or multiple doses were used), then the entire article was reviewed before a final decision was made. Fisher's χ^2 method¹¹ for combining results was used to conduct the meta-analysis.

Table I. Indications for labor induction

Indication	Placebo $(n = 53)$	$PGE_2 \ gel \ (n = 47)$	p Value
Oligohydramnios	21	11	0.08
Postterm pregnancy	5	7	0.40
Hypertension	11	13	0.42
Diabetes mellitus	7	6	0.95
Abnormal results of fetal testing	5	3	0.72
Suspected fetal growth restriction	1	2	0.60
Other	3	5	0.47

Results

Randomized, double-blind study. One hundred patients were enrolled in the study (53 received the placebo and 47 the active gel). Indications for induction of labor are shown in Table I and were similar between the two groups. There was no significant difference between the two groups with regard to race, maternal age, gestational age at the time of delivery, preapplication Bishop score, or mean birth weight (Table II). Selected pregnancy outcome parameters are listed in Table III.

During the 12-hour latent phase, uncomplicated spontaneous labor occurred in six patients, three in each group. Additionally, in two patients in the placebo group spontaneous contractions developed and a nonreassuring fetal heart rate tracing necessitated amniotomy and placement of internal monitors. Conversely, in the PGE2 group eight patients required a significant obstetric intervention during the latent period (p = 0.04). Five underwent amniotomy for fetal heart rate abnormalities after the onset of spontaneous contractions. Two patients required a cesarean delivery during the latent period, one for persistent late decelerations with spontaneous contractions and the other for worsening maternal hypertension. In one additional patient in the active gel group hyperstimulation developed but responded to vaginal irrigation and parenteral magnesium sulfate. Omitting these 16 patients (five from the placebo group and 11 from the active group), the mean change in cervical score during the latent period was 1.0 if the placebo was administered and 1.5 if the active gel was used (p = 0.16). The mean interval from placement of the gel to delivery was 28 hours in the women who received the PGE2 versus 34 hours in those who received the placebo (p = 0.08). However, two patients in the control group were omitted from the analysis; both patients received what was deemed to be an adequate trial of oxytocin induction by their attending physician but in neither case did the maternal-fetal condition warrant a cesarean delivery because of failed induction. Each patient was discharged and later readmitted in spontaneous labor. One underwent a cesarean delivery because of a labor arrest, and the other was delivered vaginally.

Table II. Population characteristics

	$Placebo \\ (N = 53)$	$PGE_2 \ gel$ $(N = 47)$	p Value
Caucasian (%)	36	36	0.97
Maternal age (yr)	23.7	24.4	0.57
Gestational age (wk)	38.5	39.1	0.31
Nulliparous (%)	62	47	0.08
Initial Bishop score	2.8	2.4	0.08
Birth weight (gm)	3142	3148	0.96

Considering the events documented here during the 12-hour latent phase and those that were observed during the subsequent induction of labor, the overall cesarean section rate in the women who received the PGE2 was 28% (13/47) as compared with 30% (16/53) in those who received the placebo (p = 0.78). There was no difference between the two groups with regard to the indications for cesarean section. Failed labor induction, dystocia, and fetal distress occurred with statistically similar frequencies. One patient in the placebo group was found to have an unsuspected breech presentation at the end of the latent period, whereas two other patients in the PGE2 group were delivered abdominally because of amnionitis and worsening maternal hypertension, respectively (as noted). All of the 100 neonates had a 5-minute Apgar score of ≥7 whereas four neonates in each group had an umbilical arterial pH < 7.2.

Complications related to the placement of the active gel were infrequent. One patient who received the PGE₂ experienced uterine hyperstimulation and fetal bradycardia, as noted above. After its resolution the patient received oxytocin and was delivered vaginally. In another patient hyperstimulation also developed; management was expectant, and she was delivered vaginally. One patient had nausea and vomiting. No patients experienced diarrhea, significant hypotension, or fever during the latent period.

Meta-analysis. A total of 18 reports that met our inclusion criteria were identified. These are listed with

selected descriptive data in Table IV. These reports included 944 treated and 867 control patients. The p value obtained from Fisher's χ^2 method was 0.85, and therefore the null hypothesis could not be rejected at the 0.05 level.

Comment

The state of the cervix is clearly related to the success of a labor induction. As Bishop¹ reported in 1964, when the cervical score exceeded 8, the incidence of vaginal delivery after labor induction was not significantly lower than that observed after spontaneous labor. Current guidelines of the American College of Obstetricians and Gynecologists state that a cervical score of at least six is considered favorable and is more likely to result in a successful labor induction. However, while the process of natural cervical ripening predicts a suc-

cessful labor induction, the effects of iatrogenic ripening are less well defined and remain under clinical investigation.

The results of our randomized study did not confirm that the use of PGE₂ gel for cervical ripening improves the success rate of an indicated labor induction. We found no significant difference in the postapplication Bishop score, the incidence of uncomplicated spontaneous labor after placement of the gel, the application-to-delivery interval, the overall cesarean section rate, and the failed induction rate. With respect to the observed gel-to-delivery time, the exclusion of two patients in the placebo group naturally affected the analysis. Conversely, significantly more patients in the PGE₂ group required a significant obstetric intervention during the gel latent period, which also may have influenced the results. Furthermore, because the placebo

[†]Excludes two control patients; see text.

^{*}Sham insertion.

group actually experienced a 12-hour idle period without a uterotonic agent, it is plausible that the immediate institution of the oxytocin infusion would have significantly shortened their time to delivery. Therefore we view the interpretation of this outcome parameter in this and other reports as problematic. Finally the inclusion of more nulliparous patients in the placebo group (p = 0.08) should have served to magnify the beneficial effects of the active gel.

We chose the total cesarean rate as the sole outcome parameter in the meta-analysis because it is the most clearly defined and unbiased end-point of a labor induction. The primary reason to perform a labor induction is to prevent a cesarean delivery; therefore any new technique advanced to modify the induction procedure should be critically examined against its influence on the cesarean delivery rate. We included only series that were based on a randomized, controlled study design because of its immunity to various biases. We limited the investigation to reports that used at least 5 mg intravaginally or 0.5 mg intracervically because, if PGE2 made a significant impact on the cesarean rate, it likely would be most notable with the higher doses. Reasonably, if the maximum doses were ineffective, lesser ones would not be expected to be more efficacious. Last, we selected only reports that used a viscous gel medium, since this kind of homogeneous mixture presumably allows controlled absorption of the PGE₂. 12 Reports that were based on the use of PGE₂ in other carriers also have appeared but were not considered because of the relative paucity of available clinical information concerning these methods.

Major limitations of meta-analysis include (1) the difficulty of locating reports that have a similar study design and that evaluate the same outcome parameters and (2) ensuring that all available reports on the subject have been considered. Nevertheless, by performing a computerized literature search, a bibliography review, a search for peer-review data presented at our two primary obstetric national meetings, and a query to the Oxford Database of Perinatal Trials, we believe that we have included the vast majority of reports that met our inclusion criteria. Still, the problem of unpublished data persists.13 We determined that it would require at least seven additional reports, each with a p value of 0.05, or 11 reports, each with a p value of 0.10, to reverse the findings of this meta-analysis. Most reports of PGE2 gel for cervical ripening have shown some benefit from its use, but the benefit most commonly has been a significant change in the cervical score. 5-6 However, this has not been a universal finding.2,7 Other clinically useful parameters, such as the time to delivery or the failed induction rate, are not universally reported and also may suffer from biases that are secondary to labor management strategies or other, sometimes arbitrary decisions by attending physicians. Whereas the incidence of serious systemic side effects from the PGE2 gel appear to be low, its tendency to induce spontaneous (sometimes hyperstimulatory) contractions^{3-6, 14} may lead to fetal compromise. If recognized, this generally can be treated with tocolytic agents or emergency delivery. Nevertheless, the potential for uterine hyperstimulation makes PGE2 gel less than the ideal cervical ripening agent. Compared with PGE2, other cervical ripening methods have been shown, in relatively small series, to have similar efficacy with less cost and fewer side effects. These include the use of mechanical dilators, 15 oxytocin infusion, 16 and extraamniotic saline solution.14 There may be an editorial bias that favors the publication of studies that demonstrate a benefit from a particular therapy¹⁷; therefore we believe that our inability to show a particular benefit (a difference in the cesarean delivery rate) from the use of PGE2 gel supports the concept that there are few unreported, positive studies that would reverse our findings.

In summary, in spite of earlier reports on the efficacy of locally applied PGE2 for cervical ripening, our data and a meta-analysis do not confirm that this technique can improve the success of an indicated induction of labor by significantly decreasing the cesarean delivery rate. Given that the use of this pharmacologic agent is not without side effects, we cannot recommend PGE2 gel for cervical priming before an indicated induction of labor.

We extend a special thanks to Malcolm Turner, Steve Bernhardt, and Brenda Henson for their help in performing this study.

Uterine rupture during trial of labor after previous cesarean section

Richard M. Farmer, MD, PhD, Thomas Kirschbaum, MD, Daniel Potter, Thomas H. Strong, MD, and Arnold L. Medearis, MD

Los Angeles, California

This study was undertaken to determine the incidence and associations of uterine rupture and dehiscence with an attempted vaginal birth after cesarean section. The charts from 137 patients who had uterine scar separation after a previous cesarean section from 1983 to 1989 were examined. Approximately 9.3% of the 119,395 women who were delivered in that interval had a prior cesarean section. Of those, 68.8% underwent a trial of labor with a 79.2% success rate. The uterine rupture rate in this latter group was 0.8%, while an additional 0.7% had a bloodless dehiscence. Bleeding and pain were unlikely findings with a uterine scar separation (3.4% and 7.6%, respectively). The most common manifestation of a scar separation was a prolonged fetal heart rate deceleration leading to operative intervention (70.3%). We conclude that, although the incidence of uterine rupture was low, the event is most often seen as an acute emergency. Prevention should be directed toward timely diagnosis and prompt management of labor dystocias. Staff and facilities for safe management of a uterine scar separation are a requisite for the conduct of a vaginal birth after previous cesarean section. (AM J OBSTET GYNECOL 1991;165:996-1001.)

Key words: Uterine rupture, cesarean section, dehiscence

The incidence of cesarean section in the United States remains at a high level, approximately 25%. Financial and medical considerations and patient preferences have initiated pressures to decrease the number of cesarean sections by promoting vaginal birth after a

6/6/31204

previous cesarean section. Counter balancing this trend is concern about a possible catastrophic scar separation during labor. Previous studies have estimated the incidence of uterine scar separation to be between 0.2% and 3.5%. 2-6 However, interpretation of incidence figures has been complicated by a lack of agreement on definitions. Uterine rupture has not been uniformly distinguished from uterine scar dehiscence. Bloodless uterine scar dehiscence has not been shown to have serious consequences for the mother or infant, whereas the effect of uterine rupture can be devastating to both.

Previous studies from this department and others⁷⁻¹⁰ have demonstrated the relative safety of a trial of labor after a cesarean section. The low incidence and small numbers of uterine ruptures, however, have precluded a comprehensive examination of this complication.

		Dehiscence		Rupture	
	n	%	No.	%·	No.
All patients with previous cesarean section	11,041	0.6	67	0.6	70
Elective repeat cesarean section	3,443	0.4	13	0.3	9
All patients with trial of labor	7,598	0.7	54	0.8	61
Successful trial of labor	6,021	0.5	28	0.1	7
Failed trial of labor (ce- sarean section)	1,577	1.7	26	3.4	54

Table I. Occurrence of scar separation in patients with previous cesarean section

This study was undertaken to examine the Los Angeles County-University of Southern California Women's Hospital experience with uterine rupture in patients who underwent a trial of labor after previous cesarean section. An attempt was made to define maternal risk factors associated with a uterine rupture.

Material and methods

The study population consisted of patients who were delivered at the Los Angeles County-University of Southern California Women's Hospital, the teaching hospital of the University of Southern California School of Medicine. Patients with a previous cesarean section who had a scar separation were identified during the period from January 1983 through December 1989 from coded medical records and department morbidity and mortality review documents. The year 1983 marked the beginning of the systematic introduction of vaginal birth after previous cesarean section. The records of 137 patients with a scar separation were retrospectively reviewed.

The patients who underwent a trial of labor had either a low-transverse, low-vertical, or unknown uterine incision. Exclusion criteria from 1983 through 1985 were an unknown uterine scar, a previous classic incision, or transverse lie that failed version. After that time, patients with unknown scars were included. Patients with multiple gestation or breech presentation were not excluded. If the patient refused a trial of labor, a repeat cesarean section was planned.

The fetal heart rate was monitored with a fetal scalp electrode or external Doppler technique. Uterine activity was monitored with an intrauterine pressure catheter when cervical dilatation allowed or with an external tocodynamometer. In each case blood was available and intravenous access established. Oxytocin and an epidural anesthetic were administered for obstetric indications. A uterine exploration was performed after each successful vaginal delivery to establish scar status. Patient management was conducted by resident physicians with staff supervision.

Uterine rupture was defined for our purposes by a modification of Donnelly and Franzoni.11 Uterine dehiscence was defined as a uterine wall defect with no emergent laparotomy, no evidence of fetal distress, and no excessive bleeding. A uterine rupture was defined as a uterine wall defect and emergency laparotomy, acute fetal distress necessitating operative intervention, or acute maternal bleeding with an estimated blood loss of >1 L.

Statistical analysis was conducted with the Crunch statistical software package (Crunch Software Corp., Oakland, Calif.). A t test was used to compare groups of patients, with p < 0.05 considered significant. Timetrend analysis was conducted with the BMDP package (BMDP Statistical Software Inc., Los Angeles) statistical software with a Cochran-Mantel-Haenszel analysis.

Results

During the period from January 1983 through December 1989 there were 119,395 deliveries at Los Angeles County-University of Southern California Women's Hospital, including 11,041 (9.3%) women with a history of a cesarean section. Of these, 7598 patients (69%) underwent a trial of labor, with 6021 (79.2%) delivered vaginally. The uterine rupture rate with a previous cesarean section was 0.6% (70 cases), whereas the uterine dehiscence rate was 0.6% (67 cases). The distribution of patients into trial of labor and elective repeat cesarean section groups is shown in Table I. In those patients who underwent a trial of labor, the incidence of uterine rupture and dehiscence was 0.8% (61 cases) and 0.7% (54 cases), respectively. The uterine rupture and dehiscence rates over the years studied are shown in Table II for patients who underwent a trial of labor.

Fetal distress was the primary indication for cesarean section in patients with a uterine rupture (85.2%, 46/54 cases), with arrest disorders second (13.0%, 7/54 cases). In patients with a uterine dehiscence, arrest disorders were the most common indication for cesarean section (69.2%, 19/26 cases), with fetal distress sec-

Table II. Incidence of scar separation in patients who underwent trial of labor after previous cesarean section, by year

		Dehiscence		Rupture	
Year	n	%	No.	%	. No.
1983	908	0.1	1	0.4	4
1984	1153	0.8	9	0.4	5
1985	1367	0.4	. 6	0.6	7
1986	1131	1.3	15	1.0	11
1987	730	0.8	6	1.2	10
1988	999	0.6	6	0.4	4
1989	1310	0.8	11	1.5	20
TOTAL	7595	0.7	(54)	0.8	(61)

Cochran-Mantel-Haenszel trend analysis; statistically significant increase in rate of uterine rupture (p = 0.003) with no significant increase in rate of uterine dehiscence.

Table III. Occurrence of uterine scar separation as function of type of previous uterine incision in patients who underwent trend of labor

Type of previous uterine incision	Dehiscence	e (n = 54)	Rupture $(n = 61)$	
	No.	%	No.	%
Low-transverse	37	68.5	29	. 47.5
Unknown	16	29.6	25	41.0
Classic	0	0	5	8.2
Vertical	1 .	1.9	2	3.3

ond (26.9%, 7/26 cases). The seven cases of fetal distress in the uterine dehiscence group were not believed to be related to the scar separation, because the dehiscences were small (<2 cm).

The type of previous uterine incision in patients who underwent a trial of labor, either low-transverse, low-vertical, classic, or unknown, is shown in Table III. The type of previous scar was identified from operative reports or by intraoperative identification of the scar site. Eleven of 115 patients (9.5%) who underwent a trial of labor had uterine rupture that was distant and separate from the previous scar.

The average number of previous cesarean sections in those patients who underwent a trial of labor was 1.4, with only four patients having more than two previous cesarean sections. Patients were not excluded from a trial of labor on the basis of the number of previous cesarean sections, nor was the indication for previous cesarean section a cause for exclusion, with the exception of a previous scar separation. In such patients a repeat elective cesarean section was recommended. The number of successful vaginal deliveries after a cesarean section is shown in Table I for the trial-of-labor population.

Oxytocin was used during the trial of labor in 73.8% of the patients with a uterine rupture and in 74.1% of the patients with a uterine dehiscence. Overall use of oxytocin during a trial of labor was 74.0% of patients

with a scar separation. An epidural anesthetic was administered during labor to 27.9% and 35.2% of the uterine rupture and dehiscence populations, respectively. The concurrent administration of epidural anesthesia and oxytocin was seen in 24.6% of the uterine rupture and 33.3% of the uterine dehiscence groups. Average labor duration in those patients with a uterine rupture was 14.8 ± 10.6 hours, whereas the average duration was 15.0 ± 8.2 hours in patients with a uterine dehiscence.

The maternal and infant variables of age, gravidity, parity, estimated blood loss, Apgar scores, birth weight, and gestational age are shown in Table IV for patients with a scar separation. Maternal morbidity and mortality as evidenced by maternal death, transfusion, urologic injury, and hysterectomy are seen in Table V. Thirteen patients were transfused, with an average of 2.7 units per patient. No patient with uterine dehiscence received a transfusion. The 15 urologic injuries consisted predominantly of intentional cystotomy or bladder laceration, with no ureteral injuries reported. Cystotomy with or without the passage of stents was most often done for the determination of ureter position or patency. Fourteen hysterectomies were performed in the uterine rupture group. Neonatal morbidity and mortality, as evidenced by neonatal death, fetal death, and neonatal intensive care unit admission, are also seen in Table V. There were no late infant

Table IV. Patient characteristics

	Dehiscence $(n = 67)$	Rupture (n = 77)
Age (yr)	27.9 ± 4.7	28.1 ± 5.5
Gravidity	3.8 ± 1.8	3.6 ± 1.7
Parity	2.1 ± 1.3	2.0 ± 1.2
Estimated blood loss (ml)	550 ± 300	1500 ± 1000
Apgar score at 1 min < 7 (%)	27.8	52:5
Apgar score at 5 min <7 (%)	5.6	27.8
Birth weight (gm)	3450 ± 600	3500 ± 500
Gestational age (wk)	40.0 ± 2.1	40.0 ± 1.8
Duration of labor (hr)	14.8 ± 10.6	15.0 ± 8.2

Values are mean ± 1 SD. Apgar scores are reported as the percentage of patients with Apgar scores <7.

deaths (>28 days) in any of the scar separation infants. All infants admitted to the neonatal intensive care unit left the hospital with the mother.

Fetal death was associated with uterine rupture and extrusion into the abdominal cavity of a 2680 gm, 40week fetus. The infant was intubated with full cardiopulmonary resuscitation for 20 minutes without success. The autopsy results were normal with the exception of petechial pulmonary hemorrhage and lack of lung aeration.

Death occurred in a 1540 gm female fetus delivered at 39 weeks. The patient was seen in labor with fetal death documented by ultrasonography. A macerated, otherwise normal infant with an autopsy-based gestational age of 32 weeks was delivered after a 7-hour labor. Uterine exploration after vaginal delivery revealed a 2 cm uterine scar separation along a previous low-transverse incision that was not repaired.

The maternal death involved a 37-year-old, gravida 3, para 1 woman who arrived with a 40-week intrauterine pregnancy and spontaneous rupture of membranes. Her obstetric history was remarkable for a cesarean birth with her last pregnancy 6 years earlier in El Salvador, performed because of failure to progress in labor. Labor was augmented with oxytocin, resulting in a 13-hour first stage of labor. The second stage of labor was 3 hours long, with delivery of a 3700 gm infant (Apgar scores of 3 and 8) facilitated by Tucker-McLane forceps. The uterus was manually explored in the delivery room, with no scar separation detected. Approximately 2.5 hours after delivery the patient had a cardiopulmonary arrest secondary to intraabdominal hemorrhage. Laparotomy disclosed a left lateral uterine rupture (approximately 10 cm) disrupting the left uterine artery; a supracervical hysterectomy was subsequently performed. Estimated blood loss was 5 L. Although the patient's initial condition was stable, there was subsequent deterioration with evidence of septic shock, consumptive coagulopathy, and extensive bronchopneumonia. She died on postpartum day 14.

The number of scar separations that were repaired

Table V. Maternal and perinatal morbidity and mortality associated with uterine scar separation in patients who underwent trial of labor

	$\begin{array}{c} Dehiscence \\ (n = 54) \end{array}$	Rupture (n = 61)
Maternal death	0	1
Transfusion	0	13 (2.7 units/patient)
Urologic injury	2	15
Hysterectomy	0	14
Perinatal death	1	1
Neonatal intensive care unit admission	1	10

Table VI. Incidence of scar separation repair in patients who underwent trial of labor

	Successful vaginal delivery	Cesarean section	Total
Dehiscence	0/28	26/26	26/54
Rupture	2/7	43/54	45/61
Hysterectomy	3/7	11/54	14/115

in patients who underwent a trial of labor is shown in Table VI. Patients who underwent elective cesarean sections all had the scar separation repaired. In trialof-labor patients who underwent a cesarean section, all scars were repaired unless it became apparent that a hysterectomy was indicated because of the extent of the scar separation or bleeding (14 of 80 patients underwent hysterectomy). In the patients who had a vaginal delivery, the scar was not repaired unless there was significant bleeding, in which case a laparotomy was performed for repair or for hysterectomy.

Subsequent pregnancies in the scar separation group were uncommon. Thirteen women were known to have had a subsequent delivery. Three of the 13 had dehiscences that were not repaired; 10 had scar separation that was repaired. The recommendation at Los Angeles County-University of Southern California Women's 1000 Farmer et al.

Table VII. Subsequent pregnancy outcome in patients with uterine scar separation

	Intact scars in subsequent pregnancy				
Pregnancy history	Cesarean section	Vaginal delivery	Total		
Dehiscence	5/6	0/1	5/7		
Rupture	4/5	1/1	5/6		

Hospital was, and is, that patients with a scar separation, repaired or unrepaired, should undergo elective cesarean section for subsequent pregnancies. The outcomes for the 13 pregnancies are shown in Table VII. It is of interest that two patients subsequently had an inadvertent trial of labor after a scar separation. One demonstrated a uterine dehiscence on uterine exploration after vaginal delivery with no further complications. The other patient had a vaginal delivery with no scar separation found on uterine exploration.

Comment

The incidence of cesarean section has been increasing for the past several decades. Patient, financial, and medical pressure to decrease this rate have led to the increased use of a trial of labor after a cesarean section. This will doubtless increase the clinician's exposure to the complications of uterine rupture and dehiscence.

The incidence of uterine rupture when the denominator is the total number of patients with a previous cesarean section is comparable to that found by other authors.³⁻¹⁰ The incidence of uterine rupture in patients undergoing a trial of labor is similar to the incidence of 0.6% derived by metaanalysis by Horowitz et al.12 but higher that found by Flamm et al.16 Overall, there is a statistically significant trend (p = 0.003) toward an increasing incidence of uterine rupture over the years of this study when the data are analyzed by the Cochran-Mantel-Haenszel method. Examination of labor duration, deviation from the labor curve, incidence of amnionitis, incidence of oxytocin use, and the number of previous cesarean sections in the population showed no statistically significant changes over the 7 years evaluated in this study. We do not have an explanation at this time for the increasing incidence of uterine rupture.

The finding of an equal incidence of uterine dehiscence and rupture is at variance with the study of Meehan et al.,18 where an approximately 2:1 ratio of dehiscence to rupture was found. The possible explanations for this discrepancy are that this study was larger in numbers and represents a more accurate estimation of the true uterine dehiscence rate or that the presence of uterine dehiscences was not as effectively appreciated by the large number of house staff examinees

participating in this study. Indeed, the maternal death involved a patient who underwent a manual uterine exploration, with a large uterine rupture not appreciated.

Fetal distress in labor as the most common indication for operative intervention in the uterine rupture group affirms observations of Meehan et al. 18 and emphasizes the need for close supervision and monitoring of these patients in labor. However, since there was only one neonatal death attributable to uterine rupture, with otherwise good perinatal outcomes, this does not support the view of Uppington,14 that fetal distress is a "late and sinister" occurrence. Rather, the findings of acute prolonged deceleration as the predominant evidence of fetal distress points to an acute event that, with prompt surgical intervention, resulted in a generally good long-term perinatal outcome. The traditional hallmarks and symptoms of scar separation, abdominal pain and bleeding, were found to occur relatively infrequently, in 3.4% and 7.6%, respectively.

Review of Tables III and IV allows an assessment of the risk factors for uterine scar separation. The type of uterine incision was different in patients with uterine rupture compared with those with a dehiscence. A known low-transverse incision predominated in the dehiscence group, and the unknown scar was more common in the uterine rupture group. A possible explanation for this might be that there was a higher incidence of previous classic cesarean sections in those patients who had a uterine rupture with an unknown scar. Many of our patients come from areas of the world where low-transverse incisions are not as common as in the United States.

Patient parity was not as high as found by other authors,18 with no difference in parity between dehiscence and rupture patients. There were no other statistically significant differences between the patients with uterine rupture and dehiscence with respect to age, gravidity, percentage of infants with a 1-minute Apgar score <7, gestational age, or birth weight. The percentage of infants with a 5-minute Apgar score < 7 was statistically greater in the uterine rupture group (p < 0.003). Whereas the patient may have had one or two previous cesarean sections, the trial of labor was overwhelmingly the first attempt for the patient. The duration of labor in the patients with a uterine rupture was not significantly different than for patients with a dehiscence, nor was the incidence of amnionitis different for the two groups.

Oxytocin use during a trial of labor remains controversial. The use of oxytocin during labor was common in patients with a uterine scar separation (74.0% overall). Since the incidence of oxytocin use during a trial of labor in patients without a scar separation is not available, no odds ratio can be calculated. Similarly, the risk of the combined use of oxytocin and regional anesthesia, thought to be a risk factor¹³ in uterine scar separation, cannot be evaluated from our data. It is possible, in some of these cases, that oxytocin was being used to stimulate a dysfunctional labor secondary to an existent scar separation. However, we believe the benefits of oxytocin use and regional anesthesia outweigh the risks when the informed patient is monitored appropriately.

The policy of this institution has been not to repair uterine dehiscences in the abscence of excessive bleeding. The short-term adverse consequences support this policy, with invariable good maternal outcome in patients so managed. However, the long-term outcome remains unclear. Only three patients with a known unrepaired uterine dehiscence have been identified as having subsequently delivered at this hospital. Two of the three patients had a repeat cesarean section, with no scar defect noted. One patient with a scar dehiscence had a subsequent inadvertent trial of labor with a resultant uterine rupture and hysterectomy. Of the 10 patients with the scar separation repaired, two had a scar separation in the subsequent pregnancy. Of interest, one patient with a repaired scar separation had a subsequent inadvertent trial of labor, with no scar separation detected on uterine exploration. The policy at this institution is also to advise patients with a previous scar separation to undergo a repeat cesarean section with the next pregnancy. In nine of 11 patients who followed this protocol, there was no evidence of scar separation at the time of the repeat cesarean section.

In conclusion, the risk of a uterine scar separation is small but finite. A trial of labor in a patient with a previous cesarean section may be conducted with minimal sequelae when the patient is continuously monitored and facilities for an emergency delivery are met. Surgical expertise and blood-banking and anesthesia services, with available urologic consultation, are mandatory to deal with the occasional patient who encounters life-threatening complications associated with a vaginal birth after a previous cesarean section.

Evaluation of obstetric ultrasonography at the first prenatal visit

Jeffrey M. Barrett, MD, and Jennifer Brinson, RNC

Lakeland, Florida

A prospective study was performed on 1000 consecutive patients to assess the value of ultrasonography at first prenatal visit. Significant ultrasonographic findings were noted in more than one third of the patients. A discrepancy between ultrasonography and menstrual dating was the most frequently noted abnormality, occurring in 27%; 59% of those would not have been discovered on initial physical examination. Other frequently noted abnormalities included missed abortion (5.7%) and twins (1.6%). The frequency of abnormalities on the initial laboratory studies recommended by the American College of Obstetricians and Gynecologists was evaluated and found to be significantly less than the frequency of clinically important ultrasonographic findings, ranging from 4.0% for positive urine cultures to 0.2% for positive serologic tests. Unexpected findings on physical examination, excluding assessment of pregnancy dating on the basis of uterine size, were even less frequent, occurring in 2.1% of the patients. It is concluded that obstetric ultrasonography at the time of the first prenatal visit is better than physical examination in evaluating the status of the pregnancy and should be considered for all patients. (AM J OBSTET GYNECOL 1991;165:1002-5.)

Key words: Obstetric ultrasonography, prenatal care, clinical obstetrics

The first prenatal visit is considered to be an extremely important time to evaluate the status of the mother and her pregnancy, including thorough medical history, physical examination, and laboratory evaluation. Although the first prenatal visit would seem to be an excellent time to more extensively assess the status of the pregnancy with ultrasonography and many offices and clinics have ultrasonography units for immediate availability, the routine use of obstetric ultrasonography at the time of the first prenatal visit has been neither fully evaluated nor recommended. This is in spite of evidence from multiple studies that have shown that ultrasonography performed in the first half of pregnancy frequently changed the gestational age as estimated by last menstrual period,1-3 enhanced early detection of twin pregnancy4,5 and missed abortion,6 and facilitated the diagnosis of fetal growth retardation.7

A prospective study was performed to evaluate the role of routine obstetric ultrasonography at the time of the first prenatal visit. Special emphasis in this study was placed on evaluating the ability to diagnose discrepancies between ultrasonography and menstrual

dating by physical examination and also to compare the frequency of clinically pertinent ultrasonographic findings with the frequency of clinically pertinent findings on physical examination and the laboratory studies recommended by the American College of Obstetricians and Gynecologists to be performed routinely at the first prenatal visit.⁸

Material and methods

A prospective study was performed on consecutive private patients presenting for a first prenatal visit. Each patient had a thorough medical history, physical examination, and obstetric ultrasonography performed in that order by a single examiner (J.M.B.). Uterine size was measured by bimanual examination in the first 12 weeks of pregnancy, by abdominal examination from 13 to 20 weeks' gestation, and by tape measure after 20 weeks' gestation. Ultrasonographic studies were performed with an Ultramark 4A real-time unit (Advanced Technical Laboratories, Bothell, Wash.). Abdominal linear-array and sector scanners and an intravaginal transducer were used as indicated for evaluation. Ultrasonographic estimation of gestational age was based on gestational sac size before 6 weeks, crownrump length from 6 to 12 weeks, and after 12 weeks the average of biparietal diameter, head circumference, abdominal circumference, and femur length. The laboratory tests were those recommended in ACOG's "Standards for OB/GYN Services," 1989.8 These tests included hemoglobin, urine culture, blood group, and Rh-type determination, antibody screen, syphilis screen, and cervical cytologic results.

Obstetricians, San Fransicso, California, January 28—February 2,

Reprint requests: Jeffrey M. Barrett, MD, Department of Obstetrics and Gynecology, The Watson Clinic, P.O. Box 95000, Lakeland, FL 33804-95000. 6/6/30915

The parameters for an inconsistency between ultrasonographic dating and menstrual dating were: before 13 weeks, >7 days; 13 to 20 weeks, >10 days; 21 to 26 weeks, >14 days; after 26 weeks, >21 days.

The parameters for an inconsistency between menstrual dating and uterine size were: before 13 weeks, >2 weeks; 13 to 26 weeks, >3 weeks, and beyond 26 weeks, >4 weeks.

Results

A total of 1000 consecutive patients were studied. In this study group 737 patients were in the first trimester, 200 in the second trimester, and 63 in the third trimester. A clinically pertinent ultrasonographic finding occurred in 36.5% (Table I).

In the 869 patients who had a viable pregnancy and who presented with what was thought to be a reliable menstrual history, 26.8% had a discrepancy between ultrasonographic dating and menstrual dating (Table II). In these patients there was believed to be no discrepancy in dating on the basis of comparison of uterine size and menstrual history in 62% in the first trimester, 48% in the second trimester, and 46% in the third trimester (Table III). The discrepancy between dating derived from ultrasonography and menstrual history had the menstrual dates greater than the ultrasonography dates in 84% of patients in the first trimester, 50% in the second trimester, and 62% in the third trimester.

Evidence of missed abortion was noted in 7.6% of all patients presenting in the first trimester. Of these patients 46% had no discordance between uterine size and menstrual dating, and 41% had not experienced bleeding.

The diagnosis of twin gestation was made in 16 patients. Twelve of these 16 uteri were large for dates on examination. Four sets of twins were diagnosed in each of the second and third trimesters, and in each case the uterine size was large for dates.

Gestational trophoblastic disease was diagnosed in three patients. Two of these patients had uterine size consistent with the menstrual dates.

Clinically pertinent abnormalities on physical examination, excluding evaluation of uterine size, were uncommon (Table IV). Of the 365 patients with abnormal ultrasonographic findings, 160 (47.0%) of these abnormalities were suspected clinically. In 25 patients, 2.9% of those with a viable pregnancy and an apparently reliable menstrual history, there was a discrepancy between uterine size and menstrual dating in spite of the fact that ultrasonographic dating was consistent with the menstrual dating. For clinical evaluation of the status of the pregnancy by pelvic examination, the sensitivity was 44%, specificity 94%, predictive value of an abnormal examination 86%, predictive value of a normal examination 72%, and efficiency 75%.

Table I. Significant abnormalities on initial ultrasonography

Abnormality	%
Discrepancy between ultrasonography and menstrual dating	26.8
Missed abortion	5.6
Twins	1.6
Uterine leiomyomas	1.2
Fetal anomalies	0.5
Gestational trophoblastic disease	0.3
Not pregnant	0.3
Ectopic pregnancy	0.1
Suspicious ovarian mass	0.1
TOTAL	36.5

Table II. Results of comparison of ultrasonographic dating with menstrual dating (N = 869)

Ultrasonographic dating	Concordance of ultrasonography and dates	Difference in ultrasonography and dates
Before 13 wk	460	180 (28.1%)
13-26 wk	138	40 (22.5%)
After 26 wk	38	13 (25.5%)
TOTAL	636	233 (26.8%)

Significant laboratory abnormalities ranged from positive urine culture (4.3%) to positive serologic test results (0.2%) (Table V).

Comment

This study evaluates all of the recommended components of the initial prenatal evaluation with the addition of obstetric ultrasonography. All medical histories, physical examinations, and ultrasonographic studies were performed by a single observer, therefore removing the potential for problems related to interobserver variation. In this report clinically pertinent findings on obstetric ultrasonography performed at the time of a first prenatal visit were noted in more than one third of all patients. This was distinctly greater than the frequency of clinically pertinent abnormalities found on physical examination and on the "routine" laboratory testing recommended to be performed at the time of the first prenatal visit. As has been reported in previous studies, ultrasonography had its highest utility in finding discrepancies in gestational age,1-3 assisting with dating the pregnancy, making the early diagnosis of missed abortion,6 and making the early diagnosis of twins.4.5

A discrepancy between menstrual and ultrasonographic dating was the most commonly noted abnormality, occurring in 26.8% of patients. Physical examination, which has been suggested to assist in making the diagnosis of gestational age discrepancy,9 was not

Table III. Frequency of compatibility of menstrual dates and uterine size when menstrual and ultrasonographic dating differed

		Uterine Size and Dates Compatible

Abnormality	%
Uterine size incompatible with menstrual dates	16.0
Suspected incompetent cervix	0.6
Abnormal thyroid	0.5
Cervical polyp	0.3
Unexpected cardiac findings	0.3
Suspicious breast mass	0.1
Signs of recent intravenous drug abuse	0.1
Severe scoliosis	0.1
Pelvic mass	0.1

Table V. Abnormal laboratory studies at first visit

Study	%
Positive urine culture	4.3
Not immune to rubella	3.9
Anemia (hemoglobin <10 gm/dl)	2.6
Positive indirect Coombs' test	0.6
Class III or IV Papanicolaou smear	0.4
Positive serologic test result	0.2

found to be particularly beneficial except when wide discrepancies between menstrual dating and ultrason-ographic dating were found. While part of this lack of benefit may be due to the study protocol, it nonetheless shows that physical examination is not precise in dating the pregnancy. While an 8- to 14-day discrepancy between dates and ultrasonography in the first trimester may not seem to be large, in selected cases this difference may be critical. This is especially true in the pregnancy complicated by premature labor, where a 1-week

discrepancy in dating could make a tremendous difference in perinatal management. There is also the obvious importance in making the correct diagnosis of the postterm pregnancy, where routine ultrasonography has been associated with a decrease in the frequency of postterm pregnancy to as low as 1.9%.\text{\text{1}} The finding in this study that most discrepancies in ultrasonographic dating and menstrual dating would postpone the estimated date of confinement as derived from menstrual history is consistent with this decreased likelihood of postterm pregnancy. Accurate pregnancy dating is also extremely important in timing repeat cesarean section, assessing fetal growth, and timing maternal serum α -fetoprotein determination.

In addition to the limitations found in making the diagnosis of a discrepancy in pregnancy dating, other limitations of physical examination assessment of the pregnancy were noted. Uterine size misjudged gestational age in 2.9% of patients where there was no discrepancy between menstrual and ultrasonographic dating and no obvious abnormality of the uterus or pregnancy. Missed abortion was associated with reassuring physical findings in almost half of cases. Only with twins did the physical examination have a high frequency of diagnosis. Because of these limitations, reliance on the first examination to fully assess the status of the pregnancy is believed to be suboptimal.

Other abnormalities found on ultrasonography also were clinically important. The early diagnosis of missed abortion allows timed uterine evacuation when required and also allows the physician to counsel the patient before the onset of bleeding, which we believe facilitates initiation of the grieving process for the pa-

tient. The importance of the early diagnosis of twins, gestational trophoblastic disease, ectopic pregnancy, and suspicious adnexal mass is straightforward.

The relatively low frequency of abnormalities noted on physical examination (except for pelvic examination) and abnormalities noted on the recommended "routine" laboratory studies should not diminish their importance. However, the comparatively high frequency of clinically pertinent findings on first-visit ultrasonography should emphasize the value of this study in initial patient evaluation.

Reasons for caution in performing routine ultrasonography include risks to the fetus, expense, and studies showing no decrease in perinatal morbidity and mortality when ultrasonography is routinely used.9-12 Currently there is no documented evidence of risk of damage to the fetus with the use of diagnostic ultrasonography.18 Evaluation of the expense of the procedure must consider both physician time and monetary costs to the patient. In an office setting where there is an ultrasonographic unit immediately available, these concerns can be addressed more readily than if ultrasonographic capabilities do not exist. In our practice a first-trimester ultrasonography is usually accomplished within 10 minutes. Studies later in pregnancy often take longer, but it is rare to cause an extensive office delay because of the performance of ultrasonography at the first prenatal visit. Because ultrasonography at the first prenatal visit is considered to be an extension of the first physical examination, it is usually performed without charge. If a patient were in a setting where an additional charge for the first prenatal visit ultrasonography is required and if she were in the first trimester, it would probably be more cost-efficient to wait until the second trimester to perform a more detailed screening ultrasonography if routine ultrasonography was to be performed. In our practice, if the first prenatal visit occurs before 16 weeks, follow-up ultrasonography is performed at approximately 20 weeks for further evaluation of the fetal anatomy. Finally, the size and design of this study did not allow assessment of changes in morbidity and mortality related to first prenatal visit ultrasonography.

This study shows that there is a high frequency of clinically pertinent findings on obstetric ultrasonography performed at the first prenatal visit, and it shows the improved accuracy of ultrasonography over physical examination to assess the pregnancy. The conclusion from this study is that the routine use of ultrasonography at the first prenatal visit is valuable and should be considered for all patients.

Patterns of uterine activity after intravaginal prostaglandin E₂ during preinduction cervical ripening

Ann M. Miller, BSN, William F. Rayburn, MD, and Carl V. Smith, MD Omaha, Nebraska

In a randomized study, uterine activity patterns were characterized with a portable pressure-sensitive device in 40 nonlaboring women at term with an unfavorable cervix who were undergoing preinduction cervical ripening with prostaglandin E₂. The prostaglandin E₂ was inserted into the posterior vaginal fornix as a single dose of either a 2.5 mg methylcellulose gel (20 cases) or 10 mg controlled-release pessary (20 cases). Uterine activity monitoring began 1 hour before dosing and continued for 12 hours. For those treated with the gel, low-amplitude, high-frequency contractions began within the first hour, reached a peak within 4 hours, and initiated sustained high-amplitude contractions in 10 (50%) cases. With the controlled-release pessary, low-amplitude, high-frequency contractions had a slightly later onset, reached a peak between the fifth and eighth hours, and initiated sustained high-amplitude contractions in 18 (80%) cases. Uterine hyperstimulation occurred in two (10%) pessary cases, with no adverse effect after removal. We conclude that low-amplitude, high-frequency uterine contractions began with either method of intravaginal prostaglandin E₂ delivery but led to sustained, high-amplitude contractions primarily with the pessary. (AM J OBSTET GYNECOL 1991;165:1006-9.)

Key words: Uterine activity, prostaglandin E2, cervical ripening

Worldwide experience has demonstrated that prostaglandin E₂ (PGE₂) administered intravaginally in low doses is of major benefit for preinduction cervical ripening. ^{1, 2} Nearly all patients experience some form of uterine contractions concurrently. Such uterine activity may be desirable if the goal is to ripen the cervix by myometrial contractions, in addition to affecting cervical connective tissues.

Uterine activity measurements made with new ambulatory tocodynamometers correlate well with those made by direct intrauterine and intracervical pressure catheters.³ Interest in monitoring methods arose from observations in patients at risk for preterm birth, in whom uterine activity may not be perceived. In our study uterine activity was characterized by use of sensitive tocodynamometers in pregnant patients at term who underwent preinduction cervical ripening.

Material and methods

After approval was granted by our Institutional Review Board, we enrolled pregnant women at term or beyond (38 to 43 weeks) who required induction of

6/6/31179

labor in spite of an unfavorable cervix (Bishop score ≤4). Indications for cervical ripening in these singleton gestations included postdates, hypertension, diabetes, and suspected fetal growth abnormalities. In all cases average uterine activity recorded beforehand was less than one contraction during a 10-minute window.⁴

As part of a continuing randomized drug trial, the PGE₂ was inserted in the form of either a 2.5 mg gel or a 10 mg controlled-release pessary. The PGE₂ gel was made in our hospital pharmacy by blending a 20 mg PGE₂ suppository with a small amount of methylcellulose gel, then frozen in a 3 ml syringe until needed. The controlled release hydrogel pessary containing a 10 mg reservoir of PGE₂ was provided by the manufacturer (PGE₂ ContRx Infusette, Controlled Therapeutics Ltd., East Kilbride, Scotland). Prior studies have proved the effectiveness of both preparations in causing cervical ripening when placed high into the vaginal canal.^{2, 5}

Each subject received a tocodynamometer (Term-Guard, Tokos Medical Corp., Santa Ana, Calif.) designed for monitoring ambulatory uterine activity. A description of the device and its dimensions, reliability, and mode of operation have been reported previously. This recording and transmission device was used to allow for ambulation without interference. Previous experience has shown the design to be particularly reliable in recording mild contractions at or near term, which predominate during the prelabor period. To ensure optimal measurement of stronger (high-amplitude) uterine contractions, a traditional in-hospital monitor

(model 115, Corometrics, Wallingford, Conn.) was used simultaneously, with the tocodynamometer held in position over the uterus above the umbilicus by an additional belt.

The study research nurse (A.M.M.) placed the monitor carefully on the patient's abdomen over the uterine fundus, an area believed to provide the most reliable information. Uterine activity was monitored for 1 hour before instillation of the PGE₂ and during seven subsequent 1-hour periods (0 to 1, 1 to 2, 2 to 3, 4 to 5, 6 to 7, 8 to 9, and 10 to 11 hours after dosing). Whereas all patients ambulated in the hospital after the first hour, recordings occurred as the patients reclined.

Monitoring data from each case were stored in the recording unit. The printout on the strip (paper speed, 3 cm/min) provided the following information: starting time and duration of monitoring, presence or absence of monitoring gaps, and warnings about any artifacts, poor connection, and end of transmission.

Four interpreters were used to assure reliability of interpretation. Uterine activity patterns as described by Sheerer et al. were characterized into two groups according to the amplitude of the contractions. Those that had an amplitude of <5 mm on the tocograph tracing and that occurred at 1- to 2-minute intervals represented a low-amplitude, high-frequency pattern. A second group of contractions consisted of those with a high-amplitude (≥6 mm), lasting at least 30 seconds and occurring less frequently. We also sought evidence for uterine hyperstimulation as described previously after PGE₂ treatment as a contraction frequency of >5 in 10 minutes or contractions exceeding a 2-minute duration. §

For each case, the proportion of time occupied by any contractions and the number of high-amplitude contractions were recorded for each hourly period. Nonparametric and parametric statistical evaluations included the χ^2 or Fisher exact test, Student t test, and analysis of variance. Results were expressed as mean \pm SD. A value of p < 0.05 was considered statistically significant.

Results

Forty women were enrolled between January and June 1990. None was excluded from data analysis. Twenty patients were assigned to the gel treatment group and 20 to the pessary group. No differences were found in demographic characteristics between the two groups (Table I).

Fig. 1 shows the mean hourly high-amplitude contraction frequencies and the proportion of time of any uterine activity (low-amplitude, high-frequency, or high-amplitude) for the two treatment groups. Both groups showed a statistically significant increase in uterine activity after dosing (Friedman analysis of variance,

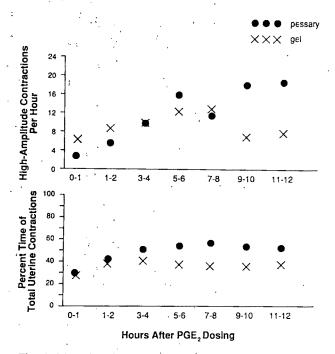

Fig. 1. Mean hourly high-amplitude contraction frequency and percent time of total uterine contractions for intravaginal PGE₂ pessary and gel-treated groups.

p < 0.001). All patients were identified as having increased uterine activity within the first hour. Both groups exhibited a crescendo of uterine activity in the first 6 hours after dosing.

For those treated with the gel, mean uterine activity reached a peak within the first 4 hours. Increases in high-amplitude uterine activity were observed in the first 1 to 2 hours after gel application and persisted during the II-hour observation period in 10 (50%) cases.

With the controlled-release pessary the peak in mean uterine activity was more delayed (at 5 to 8 hours after treatment) than with gel treatment. During the final observation period, high-amplitude contractions were observed every 3.2 ± 1.9 minutes on the average in the pessary group, compared with every 7.1 ± 2.6 minutes in the patients receiving gel (p < 0.05).

Table II illustrates the intrapartum outcomes of the two treatment groups. Labor as defined by uterine contractions leading to cervical change was initiated during the observation period in 18 (80%) of pessary cases and 10 (50%) patients receiving gel. Oxytocin was used for augmentation (in the presence of hypotonic contractions) or induction (absence of uterine contractions). Delivery within the 12-hour observation period occurred in six (30%) patients receiving the pessary and three (15%) receiving gel. Of the remaining 14 patients in the pessary group, six had sustained uterine activity by the end of the 12-hour observation period and did

not require oxytocin, as did six of 17 patients in the gel group. These differences were not statistically significant.

Uterine hyperstimulation occurred in two (10%) of the pessary cases and none of the gel cases. Its onset began at 2.8 ± 1.3 hours after dosing in multiparous patients and at 3.7 ± 2.3 hours in nulliparous patients. No adverse maternal or fetal outcomes were apparent after removal of the pessary. All infants in both groups did well with no evidence of birth asphyxia (1-minute Apgar score <7; umbilical artery pH, <7.20). All 5-minute Apgar scores were ≥ 7 .

Comment

The success of PGE₂ preparations in preinduction cervical ripening has led to a considerable interest in understanding the mechanisms of its action. Microscopic and ultrastructural studies have indicated its principal effect to be a dissolution of collagen fibers and an increase in the ground substance within the cervix.¹⁰ Increases in uterine activity are also frequently seen with use of these medications. Granstrom et al.¹¹ demonstrated myometrial activity to increase significantly during the first 3 hours after intravaginal administration of a 4 mg PGE₂ gel through a flexible, thin microtransducer in the cervical canal.

This study represents what we believe to be the first quantitative assessment of uterine activity after two methods of PGE2 administration. Low-amplitude, highfrequency, and high-amplitude patterns of contractions were measured with new ambulatory, pressure-sensitive tocodynamometers. Significant increases in total uterine activity were found with both the PGE2 gel and pessary preparations. The early peak in total uterine activity with a single dose of the PGE2 gel supports our prior clinical impressions and that reported by Granstrom et al.11 Sustained uterine activity was less predictable, and labor began in half of these patients during the preinduction observation period. In contrast, those treated with the controlled-release PGE2 pessary showed a more gradual increase in total uterine activity that peaked later, approximately 5 to 8 hours after administration. These differences would suggest that the controlled-release preparation acted by initiating labor and promoting changes in cervical connective tissue.

Although differences in mean uterine activity between the two study groups were not statistically significant, labor began in more patients with the pessary than with the gel. In these cases 80% had high-amplitude contractions at the end of 11 hours and did not require the administration of oxytocin. Although the

incidence of uterine hyperstimulation was low, it may occur more frequently with the PGE₂ pessary group, unless the pessary is removed in a timely manner.

Observations from the current study provide more precise knowledge about patterns of uterine activity with low-dose intravaginal PGE2 preparations for preinduction cervical ripening. Uterine activity may be initiated by either method of delivery, with activity persisting more frequently in the controlled-release pessary group. These findings are important when one considers the duration of electronic fetal and uterine monitoring after dosing and the potential dismissal of patients from the hospital before the scheduled induction of labor.

"Meconiumcrit" and birth asphyxia

Kenneth J. Trimmer, MD, and Larry C. Gilstrap III, MD

Dallas, Texas

Determination of the percent by volume of the solid component of meconium (the "meconiumcrit") provides a more objective method of characterizing the type of meconium. In a study of 106 women with meconium-stained amniotic fluid, 61 (58%) had thin meconium, 36 (34%) had moderate meconium, and nine (8%) had thick meconium. There was no correlation between the type of meconium and newborn acidemia (umbilical artery pH, <7.20)—13%, 19%, and 11%, respectively. None of the newborns with either thin or thick meconium had 1-minute Apgar scores of ≤3 and only two with moderate meconium had such Apgar scores; none had an Apgar score of ≤3 at 5 minutes. None of the newborns with thin or moderate meconium had meconium aspiration syndrome, although two of nine infants with thick meconium did have meconium aspiration syndrome. All newborns subsequently did well and left the hospital in good condition. There would appear to be no correlation between the consistency of meconium and recently reported criteria for defining birth asphyxia. (AM J OBSTET GYNECOL 1991;165:1010-3.)

Key words: Meconiumcrit, birth asphyxia, meconium aspiration syndrome

Meconium is often used as a marker for intrapartum or birth asphyxia and emphasis has been placed on the consistency of meconium—thin, moderate, or thick. Although some investigators believe that meconium is not associated with fetal hypoxia, acidosis, or fetal distress and indeed may even be a normal physiologic event,1-5 others have postulated that meconium is a sign of fetal hypoxia and acidosis or "intrapartum asphyxia."6-11 The diagnosis of asphyxia often rests solely on the 1- and 5-minute Apgar scores, with mild to moderate asphyxia defined as a score of 4 to 6 and severe asphyxia as a score of 0 to 3.12 However, many different factors can affect the Apgar score, including gestational age, maternal medication, anesthesia used for delivery, and the personnel assigning the score (e.g., nurse, obstetrician, or pediatrician). Another important factor that can result in a low Apgar score, especially at 1 minute, is suctioning of the trachea, a common practice in the presence of meconium. This may be especially true in the presence of thick meconium where more vigorous suctioning may be required. It is important to note that the majority of newborns diagnosed as having asphyxia on the basis of Apgar scores have no detectable neurologic or intellectual sequelae.13-16

Another criterion used in defining birth asphyxia is the presence of newborn acidemia. Traditionally, new-

born acidemia has been defined as an umbilical artery pH of <7.20.18 This level may be arbitrarily high, however, because the lower pH range in normal uncomplicated pregnancies reportedly has been as low as 7.15 to 7.10.17, 18 Although the precise value required to define acidemia is not known, umbilical artery pH values of <7.0 probably more realistically represent clinically significant acidosis. 19, 20 Because asphyxia implies hypoxia leading to metabolic acidosis, the presence of acidemia at birth may provide a more objective method to evaluate the significance of meconium-stained amniotic fluid. The purpose of this study was to evaluate the association of the consistency of meconium as measured by the "meconiumcrit" and currently accepted markers of birth asphyxia, namely, the I- and 5-minute Apgar scores, umbilical artery cord blood pH, and newborn seizures.

Material and methods

Patients were included in this study if they were at term (birth weight, >2500 gm) and had meconiumstained amniotic fluid. There were 106 such women who had a 10 ml sample of amniotic fluid collected by an intrauterine pressure catheter after the first 10 ml was discarded. In addition to this sample, 57 women also had a second 10 ml sample of amniotic fluid collected by bedpan at the time of amniotomy to determine if the intrauterine catheter would diminish sample quality or quantity. All amniotic fluid specimens were placed in glass tubes and centrifuged at 1000 revolutions/min for 10 minutes. The meconiumcrit was measured by dividing the solid volume by the total volume, as with hematocrit, and the samples were graded as thin, moderate, and thick according to the solid component by volume (<10%, 10% to 30%, and 30%, re-

Thick	10	9	9	8

Spearman's $\rho = 1.00$; Pearson's r = 0.997; p = 0.047.

spectively). The cutoffs for percent solid component for defining the three groups were arbitrarily selected before initiation of the study. Meconium also was graded subjectively as thin, moderate, or thick by the physicians in attendance but was unknown at the time of centrifugation and grading according to the meconiumcrit. Umbilical artery blood gas analysis was performed in all newborns. All samples were drawn immediately from a doubly clamped segment of umbilical cord at delivery, placed into ice, and transported directly to the laboratory for analysis. As is our delivery room policy, the obstetrician immediately suctioned the oropharynx with a bulb syringe after delivery of the fetal head. Pediatric house staff attend all deliveries complicated by meconium, and the vocal cords are visualized with a laryngoscope, followed by suctioning by a DeLee catheter. The designation of meconium below or above the vocal cords was based on pediatric assessment in the delivery room. The subsequent diagnosis of meconium aspiration syndrome was based on characteristic x-ray findings and the clinical course of the infant in the special care nursery. Apgar scores were assigned by the pediatric house staff in attendance. We stratified the umbilical pH results and Apgar scores into several groups. Statistical comparison was performed with the χ^2 test or Fisher's exact probability test where appropriate.

Results

With the use of the percent solid component by volume (i.e., the meconiumcrit), there were 61 (58%) patients with thin meconium, 36 (34%) with moderate meconium, and nine (8%) with thick meconium. The correlation of the degree of meconium as determined clinically compared with the meconiumcrit is summarized in Table I.

In addition, there was no difference in meconiumcrit on the basis of sample collection methods, bedpan versus intrauterine pressure catheter (Spearman's $\rho = 1.00$; Pearson's r = 0.998, p = 0.047). Three (5%) of the infants with thin meconium, six (14%) of the infants with moderate meconium, and two (22%) of the infants with thick meconium had 1-minute Apgar

scores <6 (Table II). Only two (6%) of the infants in the moderate meconium group had a 1-minute Apgar score ≤3. None of the infants with thin or thick meconium had Apgar scores ≤3 at 1 minute. One of the infants with thin meconium, one with moderate meconium, and one with thick meconium had 5-minute Apgar scores <6. None of the 106 infants had a 5minute Apgar score ≤3.

The average mean umbilical artery pH of the 106 infants was 7.25; this did not significantly vary among the three groups (Table III). Eight (13%) of the infants with thin meconium, seven (19%) with moderate meconium, and one (11%) with thick meconium had an umbilical artey pH of <7.20. No infant in the study had an umbilical artery pH of <7.00, a more accurate reflection of significant newborn acidemia. Also there were no infants with an umbilical artery pH <7.20 who also had a 5-minute Apgar score <6.

Statistical comparison of each of these parameters

including 1- and 5-minute Apgar scores, mean umbilical artery pH, frequency of newborn acidemia, occurrence of meconium aspiration, and newborn seizures did not reveal any significant differences among the three groups.

All the infants were born alive and there were no neonatal deaths. Meconium aspiration syndrome developed in two infants with thick meconium. The infants were treated with aggressive airway management and subsequently did well. None of the 106 infants suffered from newborn seizures.

Comment

Mitchell et al.,¹⁰ in a study of 53 women with moderate to thick meconium, reported that 53% of the newborns were acidotic at birth and the majority of them had metabolic acidemia. These authors further stated that meconium below the cords was associated with fetal metabolic acidosis and neurologic depression, implying intrapartum asphyxia. A relatively high umbilical artery pH cutoff of 7.25 was used to define acidemia in this study, and the criteria used to define metabolic acidemia were not given. Moreover, moderate to thick meconium was subjectively defined according to color of the amniotic fluid.

In an attempt to more objectively assess the meconium content of amniotic fluid, Weitzner et al.21 reported a technique for quantifying amniotic fluid, termed the meconiumcrit. These authors used a 3.0 gm specimen of meconium obtained from a newborn and diluted it with various quantities of amniotic fluid to obtain concentrations ranging from 1.5 to 10.0 gm/100 ml. They used standard hematocrit tubes for determining the meconiumcrit. While we agree that this technique is both simple and reproducible in a laboratory setting, we found it somewhat more difficult to use standard hematocrit tubes in the presence of meconium with particulate matter in a clinical setting. Thus we chose both a larger sample and larger tubes that were spun undiluted. Although our criteria for defining the three groups according to the meconiumcrit were arbitrarily selected, there was excellent correlation (r = 0.997) with the subjective assessment by the physician in attendance during labor and delivery.

In a previous report from our institution of 323 term pregnancies with meconium-stained amniotic fluid (incidence, 18%), Yeomans et al.²² reported that 21% of the newborns had an umbilical artery pH of <7.20, 7% had a pH <7.15, and none had a pH <7.00. There was no correlation between the type of meconium on the basis of the clinical estimate and pH results in this study. Using a more objective method of characterizing the type of meconium (i.e., the meconiumcrit), we likewise found no correlation between the character or type of meconium and the frequency of acidemia (defined

as either an umbilical artery pH <7.20 or <7.00), the type of acidemia (respiratory or metabolic), or low (\leq 3) 1- or 5-minute Apgar scores. Two of the nine newborns with thick meconium did have meconium aspiration syndrome; however, both were normal at discharge. Considering that only 2% of all newborns in most published series will have meconium aspiration syndrome, the determination of thick meconium by the meconiumcrit may prove a useful predictor of risks for this complication. However, the number of infants with thick meconium in this study is not large enough to address this issue in a statistical manner.

In conclusion, the percent solid component by volume of meconium as determined by the meconiumcrit would appear to provide an accurate method of assessment of the character or type of meconium. Using recently reported criteria to define birth asphyxia such as an umbilical artery pH of <7.00, an Apgar score of ≤3, and newborn neurologic dysfunction (i.e., seizures), there would also appear to be no correlation between the type of meconium and birth asphyxia.

The relationship between umbilical artery Doppler velocimetry and fetal biometry

William E. Scorza, MD, Deborah Nardi, RT(R), RDMS, Anthony M. Vintzileos, MD, Alfred D. Fleming, MD, John F. Rodis, MD, and Winston A. Campbell, MD

Farmington, Connecticut

The relationship between peak-systolic/end-diastolic ratio of the umbilical artery waveform and fetal biometry was studied in 127 uncomplicated pregnancies with established dates between 20 and 40 weeks' gestation. At each ultrasonographic examination fetal biometry included measurement of the biparietal diameter, head circumference, abdominal circumference, and femur length. The peak-systolic/end-diastolic ratio was measured by either a continuous or a pulsed-wave method. There were significant linear negative correlations between all the biometric parameters, as well as between the ultrasonographically estimated fetal weight and peak-systolic/end-diastolic ratio. Of the individual ultrasonographic parameters the femur length (for gestations <30 weeks) and the abdominal circumference (for gestations ≥30 weeks) were found to be best correlated with the peak-systolic/end-diastolic ratio. Regression curves, including the 10th and the 90th percentile, were developed between each biometric parameter (biparietal diameter, head circumference, abdominal circumference, and femur length), as well as between estimated fetal weight and peak-systolic/end-diastolic ratio. The estimated fetal weight nomogram had the best sensitivity (48%) in predicting intrauterine growth retardation. These nomograms should prove most useful in assessing downstream placental vascular resistance in high-risk patients with unknown dates. (AM J OBSTET GYNECOL 1991;165:1013-9.)

Key words: Umbilical artery velocimetry, fetal biometry

Continuous or pulsed-wave Doppler ultrasonography of the fetal umbilical artery has been increasingly used in clinical obstetrics in the management of highrisk pregnancy. ¹⁻³ The measurement of the peak-systolic/end-diastolic ratio of the umbilical artery flow velocity waveform is the most commonly used method. Abnormal ratios have been associated with an increased incidence of neonatal morbidity, mortality, and intrauterine growth retardation. ^{4, 5} The abnormal wave-

forms are believed to be the result of increased downstream placental vascular resistance and therefore of impaired placental perfusion.⁶ The proper use of the umbilical artery peak-systolic/end-diastolic ratio, however, requires knowledge of the length of gestation, which is unknown or unavailable in 20% to 40% of pregnant patients.7 When the last menstrual period is unknown or uncertain, extrapolation of gestational age on the basis of fetal biometric data may lead to erroneous interpretation of the peak-systolic/end-diastolic ratio results, because there are no data regarding the relationship between the umbilical artery peak-systolic/end-diastolic ratio and fetal biometry. Therefore the purpose of the present report was: (1) to study the relationships and generate regression curves between the peak-systolic/end-diastolic ratio and the most commonly used fetal biometric parameters (biparietal di-

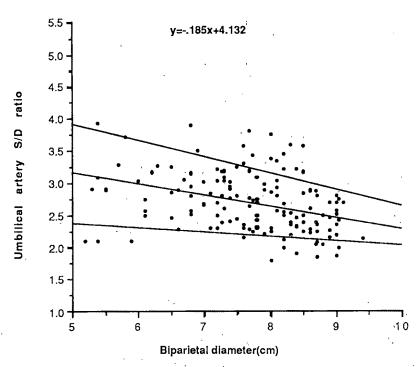

Fig. 1. Scattergram illustrating relationship (along with 10th, 50th, and 90th percentile lines) between umbilical artery peak-systolic/end-diastolic ratio (S/D) and biparietal diameter (R=0.395, p=0.0001).

ameter, head circumference, abdominal circumference, femur length, and estimated fetal weight); (2) to assess which fetal biometric parameters, if any, are significantly correlated with the peak-systolic/end-diastolic ratio; and (3) to determine the sensitivity of the fetal biometric parameter nomograms to predict intrauterine growth retardation (IUGR).

Material and methods

Patients were recruited from those referred to our antepartum fetal evaluation unit at the University of Connecticut Health Center. We used 127 uncomplicated pregnancies between 20 and 40 weeks of gestation (dates confirmed by early ultrasonography) for a single ultrasonographic assessment. The patients were referred for confirmation of clinical dates or fetal size. Patients were selected if they had initiated prenatal care early in pregnancy, if they had regular menstrual cycles with reliable menstrual dates, and if the results of ultrasonographic examination were consistent with their menstrual dates. All patients had intact membranes and singleton pregnancies. Patients were excluded if fetal anomalies were detected or if the estimated fetal weight was <-2 SD or >2 SD from the mean for gestational age.8

The ultrasonographic examinations were performed, using a model 128 (Acuson, Mountain View, Calif.) or a model 3000 or 2600 (General Electric, Rancho Cordova, Calif.). A 3.5 or 5 MHz linear-array trans-

ducer was used. All machines had freeze-frame capabilities and electronic calipers for measurement. The ultrasonographic velocity was 1540 m/sec. The study was cross-sectional, and each patient was included only once. Routine measurements (biparietal diameter, head circumference, abdominal circumference, and femur length) were obtained and recorded on each patient. The biparietal diameter and head circumference measurements were obtained from an axial scanning plane at the level of the thalami. The fetal abdominal circumference was taken perpendicular to the long axis of the fetal body at the level of the ductus venosus complex. The abdominal circumference was measured directly with electronic calipers or predominantly by using the formula $D1 + D2 \times 1.57$, where D is diameter (both methods have been shown to give equivalent results).9 The femur length was measured according to the technique described by O'Brien and Queenan.10 The ultrasonographic estimated fetal weight was calculated by averaging the estimated fetal weight obtained by both Shepard's (using biparietal diameter and abdominal circumference)11 and Hadlock's (using abdominal circumference and femur length)12 formulas. The umbilical artery peak-systolic/end-diastolic ratio was obtained transabdominally by continuous (model 5000A, Multigon, Mount Vernon, N.Y.) or pulsed-wave (model 128, Acuson) Doppler ultrasonography. All studies were performed during fetal apnea. The peak-systolic/end-diastolic ratios of three waveforms from three

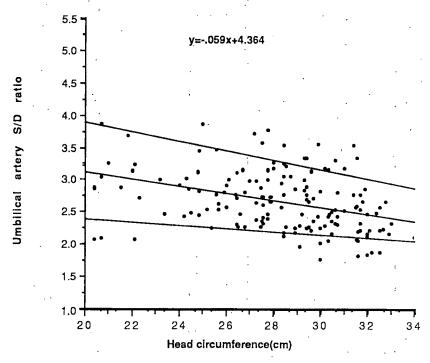

Fig. 2. Scattergram illustrating relationship (along with 10th, 50th, and 90th percentile lines) between umbilical artery peak-systolic/end-diastolic (S/D) ratio and head circumference (r = 0.422, p = 0.0001).

different sampling sites were computed, and the mean ratio was used in the analysis.

Scattergrams of the peak-systolic/end-diastolic ratio values versus gestational age and fetal biometry were developed. Regression analyses were used to establish nomograms, including the 10th, 50th, and 90th percentile lines. To assess which fetal biometric parameter(s), if any, best correlated with the peak-systolic/enddiastolic ratio, multiple regression analyses and stepwise regression analyses were used. A p value < 0.05. was considered statistically significant. The statistical analysis of the data was performed by computer (Macintosh II) with the Stat View 512+ (Abacus Concepts, Berkeley, Calif.) and CricketGraph (Cricket-Graph, Malvern, Pa.) statistical packages.

During the study period there were 25 patients with known dates (based on last menstrual period and confirmed by early ultrasonography) who had growthretarded fetuses (estimated fetal weights < -2 SD from the mean for gestational age).8 The gestational ages of these fetuses ranged from 26 to 38 weeks. The fetuses were used to determine the sensitivity of the newly constructed nomograms on the basis of fetal biometry, to predict growth retardation. In all 25 fetuses the diagnosis of IUGR was confirmed after birth.

Results

The study population consisted of 127 patients with gestational age (mean \pm SD) of 31 \pm 4 weeks (median,

31.1). Of these, 104 (81%) were white, 12 (10%) black, and 11 (9%) Hispanic. Seventy patients (55%) were nulliparous and 57 (45%) were multiparous. The maternal age (mean \pm SD) was 26.3 \pm 5.6 years (range, 15 to 40). The best-fit curves between peak-systolic/enddiastolic ratio and biparietal diameter, head circumference, abdominal circumference, femur length, and estimated fetal weight were linear. The r values were 0.395, 0.422, 0.461, 0.453, and 0.460, respectively (all p values were = 0.0001). The scattergrams, including the 10th, 50th, and 90th percentile boundaries, and the regression equations are illustrated in Figs. 1 to 5. The estimated fetal weight had the highest linear negative correlation with the peak-systolic/end-diastolic ratio (r = 0.461). The best-fit curve between the peaksystolic/end-diastolic ratio and gestational age also was linear (Fig. 6).

To determine the origins and to assess which fetal biometric parameters contribute to this negative correlation between estimated fetal weight and the peaksystolic/end-diastolic ratio, the data were analyzed according to two gestational age groups, <30 weeks' gestation (46 patients) and ≥30 weeks' gestation (81 patients). In both gestational age groups there was a significant linear negative correlation between estimated fetal weight and the peak-systolic/end-diastolic ratio (p < 0.05 and p < 0.0005, respectively). To assess which ultrasonographic parameter(s) significantly correlated with the peak-systolic/end-diastolic ratio within

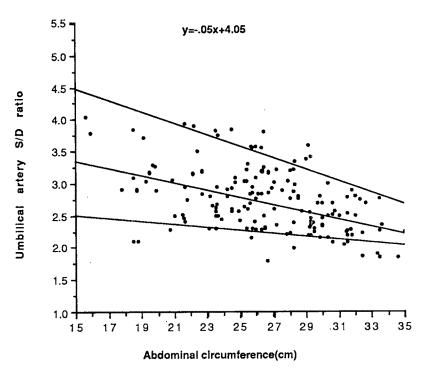

Fig. 3. Scattergram illustrating relationship (along with 10th, 50th, and 90th percentile lines) between umbilical artery peak-systolic/end-diastolic (S/D) ratio and abdominal circumference (r = 0.460. p = 0.0001).

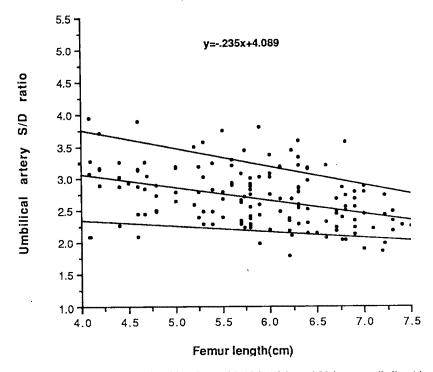

Fig. 4. Scattergram illustrating relationship (along with 10th, 50th, and 90th percentile lines) between umbilical artery peak-systolic/end-diastolic (S/D) ratio and femur length (r = 0.453, p = 0.0001).

each gestational age group. multiple regression analyses and stepwise regression analyses were used with the peak-systolic/end-diastolic ratio used as the dependent (outcome) variable and biparietal diameter, head

circumference, abdominal circumference, and femur length used as the independent (predictors) variables.

Multiple regression analysis of the group <30 weeks' gestation revealed that the overall association was sig-

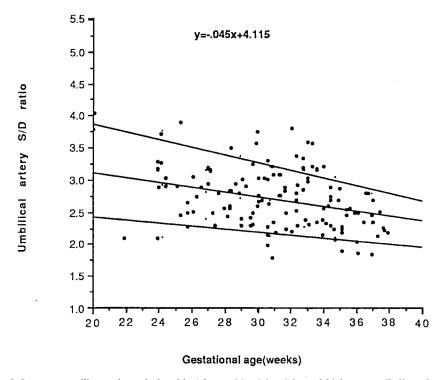

Fig. 6. Scattergram illustrating relationship (along with 10th, 50th, and 90th percentile lines) between umbilical artery peak-systolic/end-diastolic ratio and gestational age (r = 0.391, p = 0.0001).

nificant (p < 0.05). Of the four independent variables, only femur length was significantly correlated with the peak-systolic/end-diastolic ratio (p < 0.05; β coefficient, -0.477; standard error, 0.211; standard coeffi-

cient, -0.673; t value, 2.262). Stepwise regression analysis of this group of fetuses of <30 weeks' gestation also indicated that the femur length was the only independent variable to enter the equation (r = 0.477, $R^2 = 0.227$, adjusted R^2 ; = 0.21). Similar analyses were performed for the group of fetuses with gestational ages ≥30 weeks. With multiple regression analysis it . was found that the overall correlation of the independent variables to the peak-systolic/end-diastolic ratio was significant (p < 0.0005). Of the individual independent variables only abdominal circumference was significantly associated with the peak-systolic/end-diastolic ratio (p < 0.005; β coefficient, -0.086; standard error, 0.03; standard coefficient, -0.534; t value, 2.896). Stepwise regression analysis also was performed, and only the abdominal circumference entered equation $(r = 0.525, R^2 = 0.276, \text{ adjusted})$ $R^2 = 0.267$). The same analyses were repeated with gestational age included as one of the independent variables, but the results were the same. Even when gestational age was used as one of the independent variables, only femur length for fetuses <30 weeks' gestation and only abdominal circumference for fetuses ≥30 weeks' gestation again were the only variables significantly correlated with the peak-systolic/enddiastolic ratio.

With the established nomograms between the peaksystolic/end-diastolic ratio and the fetal biometric parameters, the sensitivity of each parameter to detect IUGR was calculated. The gestational age of the fetuses with IUGR was $32.7 (\pm 3.6)$ weeks (median, 33). Two of the fetuses had absent end-diastolic velocities and were excluded from calculations of sensitivity. The sensitivity of detecting growth retardation by using the biparietal diameter nomogram was 35% (8/23), head circumference 35% (8/23), abdominal circumference 35% (8/23), femur length 30% (7/23), and estimated fetal weight 48% (11/23). Of these ultrasonographic parameters, the estimated fetal weight versus the peaksystolic/end-diastolic ratio had the best sensitivity. The sensitivity by using the gestational age versus the peaksystolic/end-diastolic ratio nomogram was 52% (12/23).

Comment

In 1978 McCallum et al.¹⁸ suggested that umbilical artery velocity waveforms could be recorded by ultrasonographic Doppler probes. Subsequently various investigators suggested that the calculation of peak-systolic/end-diastolic ratio of the umbilical artery velocity waveform reflects placental vascular resistance.⁶ Elevated ratios have been associated with an increased incidence of adverse perinatal outcome, such as growth-retarded infants who are prone to hypoxic complications, twin-to-twin transfusion, and preeclampsia.^{4, 5, 14, 15} It has been clearly shown from previous investigations that there is a steady decline in the peak-systolic/end-diastolic ratio with advancing gestational age, ^{16, 17} the length of gestation should be known for the accurate interpretation of the ratio result. How-

ever, the last menstrual period is unknown or uncertain in approximately 20% to 40% of pregnant patients.⁷

This is the first report to evaluate the relationships and establish nomograms between each of the most commonly used ultrasonographic parameters (biparietal diameter, head circumference, abdominal circumference, femur length) and the estimated fetal weight and peak-systolic/end-diastolic ratio. Statistically significant relationships were found between the ratio and each of the ultrasonographic parameters as well as the estimated fetal weight. There was an inverse relationship between the ratio and each ultrasonographic parameter. The use of these gestational age-independent nomograms may prove useful for evaluating placental resistance in patients with unknown dates or late registrants with uncertain dates. In the 23 fetuses with IUGR encountered during the study period, the sensitivity of the fetal biometry versus the peak-systolic/end-diastolic ratio nomograms to detect IUGR was not significantly different from that with the gestational age versus the peak-systolic/end-diastolic ratio nomogram. The best sensitivity was achieved by the estimated fetal weight versus the ratio nomogram (48%), which compared quite favorably with the sensitivity obtained by using gestational age (52%). The detection of an abnormally high peak-systolic/end-diastolic ratio in growth-retarded fetuses depends on whether small fetal size is the result of impaired uteroplacental blood flow or nonplacental causes. Furthermore, even with uteroplacental insufficiency the ratio still may be normal in some cases. Therefore it is not surprising that the sensitivity of detecting IUGR by our method is approximately 50% because many of the fetuses that weigh <10th percentile for gestational age may suffer lesser-degrees of uteroplacental insufficiency or the low weight may be the result of nonplacental causes.

Of interest were the results of the multiple and stepwise regression analyses that used the peak-systolic/end-diastolic ratio as the dependent (outcome) variable and the remaining ultrasonographic biometric parameters as the independent variables. One of the most interesting results of this study was the only significant correlation of femur length to the peak-systolic/enddiastolic ratio for fetuses <30 weeks and of abdominal circumference to peak-systolic/end-diastolic ratio for fetuses ≥30 weeks. These findings persisted even when the gestational age was included as one of the independent variables. The explanation for these findings lies in the fact that femur length is an indirect measure of fetal length and abdominal circumference is an indirect measure of fetal body weight. It is already known that the fetus exhibits two growth spurts, one in fetal length during the second trimester and the other in body weight during the third trimester. 18, 19 A breakpoint of 30 weeks was chosen in the analysis of the data because, as has been previously shown,18,19 the fetal

growth spurt in length has been almost completed while the growth spurt in weight has just begun by 30 weeks of gestation. Therefore it is not surprising to find a significant correlation between femur length, which represents fetal length, and the peak-systolic/end-diastolic ratio at gestational ages <30 weeks and between abdominal circumference, which represents fetal body weight, and the peak-systolic/end-diastolic ratio for gestational ages ≥30 weeks. It can be speculated that the lower the ratio, the lower the vascular placental resistance and thus the higher the uteroplacental blood flow, resulting in increased fetal growth, which is reflected by increased fetal length (or femur length) during the second trimester and increased body weight (increased abdominal circumference) during the third trimester. The finding of best correlation between the peak-systolic/end-diastolic and the femur length in gestations <30 weeks (and between the peak-systolic/enddiastolic ratio versus abdominal circumference in gestations ≥30 weeks) should not be interpreted that the femur nomograms should be used at <30 weeks and the abdominal circumference nomograms at ≥30 weeks. Our data simply suggest that the estimated fetal weight nomogram is similar to the gestational age nomogram, which is used widely, and that the greatest sensitivity for IUGR is achieved when the estimated fetal weight nomogram is used. As far as the clinical relevance of the other nomograms, (biparietal diameter, head circumference, abdominal circumference, and femur length vs the peak-systolic/end-diastolic ratio), these may be used in patients with fetal congenital anomalies that preclude the use of the estimated fetal weight nomogram (i.e., hydrocephalus, skeletal dysplasias, hydrops, etc.). In such cases a judgment should be made as to which biometric parameter is not affected by the fetal malformation, and the corresponding nomogram should be used.

In summary, this study supports the use of gestational age-independent nomograms with fetal biometry versus the peak-systolic/end-diastolic ratio used to detect fetuses with increased placental vascular resistance. The use of these nomograms should prove useful in evaluating patients with unknown dates. It also sheds some light into the relationship between fetal biometric parameters and placental vascular resistance. Placental vascular resistance as determined by the peak-systolic/end-diastolic ratio is more closely correlated with fetal size parameters than with gestational age. The fact that appropriately grown fetuses of the same gestational age may have different peak-systolic/end-diastolic ratios may be due to differences in placental vascular resistance and therefore nutrition. To investigate this possibility the next logical step should be an assessment of the correlation between fetal biometry and the peak-systolic/end-diastolic ratio in fetuses of the same gestational age. The value of the fetal biometric nomograms to assess IUGR is currently being investigated at our institution in a prospective manner.

Risk factors for cordocentesis and fetal intravascular transfusion

Carl P. Weiner, MD, Katharine D. Wenstrom, MD, Susan L. Sipes, MD, and Roger A. Williamson, MD

Iowa City, Iowa

There is little information on the impact of technical aspects or patient characteristics on the risks of accessing the fetal circulation. We performed 594 diagnostic cordocenteses and 156 intravascular transfusions over 6 years. Pancuronium was administered during 52% of procedures. The number of needle punctures per successful procedure was unrelated to the placental location. However, the number of punctures required was lower if the placental cord origin rather than a midsegment was targeted (p < 0.0001). Bleeding from either the uterine or umbilical cord puncture site was not believed to be clinically significant, although the duration of bleeding was greater after arterial puncture than after venous puncture (p = 0.01) and after intravascular transfusion than after diagnostic cordocentesis (p < 0.0001). Amnionitis (suspected plus verified) complicated 0.5% of procedures. Preterm premature rupture of membranes (with or without amnionitis) followed 0.4% of procedures. Fetal bradycardia occurred in 6.6% $(6.6 \pm 0.8 \text{ minutes})$; range, 0.1 to 35 minutes). There were five perinatal losses after a diagnostic procedure, yielding an uncorrected loss rate of 0.8% (5/594). Each was associated with a prolonged bradycardia; each fetus was ultimately demonstrated to have been unsalvageable. Two independent risk factors for bradycardia were identified-arterial puncture and severe, early onset intrauterine growth retardation. The administration of pancuronium reduced the incidence of bradycardia in appropriately grown fetuses (6% to 1.5%; ρ < 0.05), but did not alter the incidence in growth-retarded fetuses. We conclude that cordocentesis performed with a needle guide is a safe procedure but that its risk varies with both the indication and the vessel punctured. (AM J OBSTET GYNECOL 1991;165:1020-5.)

Key words: Pregnancy, cordocentesis, fetal intravascular transfusion, complications

Since first reported in 1983,1 ultrasonographically guided percutaneous access of the fetal umbilical circulation has become common. The potential applications of the procedure, variously called cordocentesis, percutaneous umbilical blood sampling, or funipuncture, are many.2 However, as with any obstetric procedure, these applications will be limited by the associated perinatal morbidity and mortality. Several investigators have reported global perinatal loss rates for cordocentesis,⁸⁻⁷ but there is little information as to whether technical aspects of the procedure or patient characteristics have an impact on the risk. A prior report from this unit after our first 100 diagnostic cordocenteses noted that the risk of fetal bradycardia was higher after arterial puncture than after venous puncture.3 The purpose of this investigation was to determine, from a 6-year experience encompassing 750 diagnostic and therapeutic procedures, what factors were associated with an adverse outcome.

Material and methods

The fetal circulation was accessed 750 times (594 diagnostic cordocenteses in 375 pregnancies, 156 intravascular transfusions in 54 pregnancies) for a wide variety of indications.3 The techniques for cordocentesis and intravascular transfusion have been previously detailed.^{8, 8} Each used a 22-gauge spinal needle held in the ultrasonographic plane of a 5 MHz sector transducer by a fixed needle guide (Civco, Kalona, Ia.). With this apparatus, needle movement was limited to the vertical plane. The placental origin of the umbilical cord was the preferred target, unless the indication was red blood cell alloimmunization and the placenta was anterior. In that instance, or when the placental umbilical cord origin was not readily identified or if access was blocked by either a fetal part or the umbilical artery, a free-floating loop of cord away from the placenta with the umbilical vein in an anterior position was targeted. The fetal cord origin was rarely selected because of its proximity to the body and because it is innervated. Pancuronium (0.3 mg/kg estimated fetal weight) was administered intravenously whenever fetal movement

was believed to pose a risk. The pressure of both the vessel punctured and the amniotic cavity were routinely measured, as previously described, through the same puncture.9, 10 The vessel punctured was definitively identified by a combination of the ultrasonographic image, the vessel blood pressure, and the direction traveled by an injected saline solution bolus. With the described methods diagnostic cordocentesis (including blood and amniotic cavity pressure measurement) was completed within 90 seconds of uterine puncture and intravascular transfusion was accomplished within 45 minutes. Prophylactic antibiotic therapy was not given. Transfusions were undertaken when the fetal hematocrit declined below 30% and consisted of red blood cells suspended in normal saline solution to yield a hematocrit of 70%.8 Five physicians performed the procedures described, although 83% were performed by one individual (C.W.).

All procedures were preceded by a detailed ultrasonographic examination that included interrogation of the umbilical artery with pulsed gated Doppler (General Electric 3600, Rancho Mirage, Calif.). At least three waveforms between fetal respirations were measured and the result was averaged. By convention, a systolic/diastolic ratio of ≥10 was assigned a value of 10.11

A complete blood cell count was performed on blood anticoagulated with ethylenediametetraacetate (Technicon H-1). The umbilical pH, PcO2, and PO2 were measured in heparinized blood (Instrumentation Laboratory) within minutes of the sample aspirations.

Severe, early onset intrauterine growth retardation was defined as either that ultrasonographically detectable by 32 weeks' gestation or symmetric growth retardation detected at any length of gestational age.12 In our unit this requires both an abdominal circumference percentile below 2.5 and an estimated weight percentile below 10.

A record of each procedure was maintained prospectively in a computerized data base whose accuracy was verified on a regular basis. This record included, in addition to the laboratory parameters, the indication(s) for the procedure, gestational age, placental location, the operator, number of successful and failed punctures, the location of the punctures, the vessel punctured, the duration of fetal bradycardia (heart rate <100 beats/min), the duration and site of bleeding, rupture of membranes within 2 weeks of the procedure, the need for emergency delivery, and perinatal loss. Results are presented as the mean \pm 1 SD unless otherwise stated. Statistical analyses included paired and unpaired t tests, Fisher's exact test, and stepwise multiple regression. A $p \le 0.05$ was considered to indicate either a significant difference between two means or the presence of a significant relationship between two variables.

Results

The most common indications per diagnostic procedure and per patient are shown in Table I. Indications for fetal transfusion included alloimmunization (n = 141), human parvovirus infection (n = 2), twintwin transfusion (n = 10), and fetal-to-maternal hemorrhage (n = 3). The mean \pm SD gestational age at the time of the procedure was 28.4 ± 5 weeks (range, 16 to 42 weeks). Sixty percent (n = 450) of procedures were performed at the placental cord origin, 38% (n = 283) in a free-floating loop of cord, and 2% (n = 17) at the fetal cord origin. There were no differences in the distribution of puncture sites between diagnostic and therapeutic procedures. Pancuronium was administered during 52% of the procedures. All transfused fetuses received pancuronium.

The mean number of skin insertions per successful procedure was 1.5 ± 0.8 . A third of aborted skin punctures were stopped before the needle entered the amniotic cavity. The number of punctures was unrelated to placental location and operator experience but was significantly lower when the placental cord origin was targeted, compared with all other locations (1.3 \pm 0.8 vs 1.7 ± 1 ; p < 0.0001).

Bleeding occurred from both uterine (12%) and umbilical cord (29%) puncture sites. Twenty fetuses had a platelet count <50,000/µl³; eight had a count <10,000/µl3. There was no correlation between the fetal platelet count and either the incidence or the duration of bleeding from the puncture site, even when the analysis was confined to fetuses whose platelet counts were <100,000/µl³. When bleeding did occur, the mean duration was greater after transfusion $(0.36 \pm 0.9 \text{ minutes})$ than after a diagnostic cordocentesis (0.13 \pm 0.3 minutes; p < 0.0001). Furthermore, the duration of bleeding from the puncture site was longer after arterial puncture than after puncture of the umbilical vein for both diagnostic and therapeutic procedures (each p = 0.01). The duration of bleeding from the uterine wall did not vary by the vessel punctured, but it was longer after transfusion than after cordocentesis (0.24 \pm 0.9 vs 0.10 \pm 0.4 minutes; p = 0.004). There was no direct or indirect evidence that any of the blood loss was clinically significant.

Culture-proved amnionitis (N = 3) and suspected amnionitis (N = 1) occurred after diagnostic (N = 2)and the rapeutic (N = 2) procedures. Three of the four followed a procedure that had required a single puncture and one followed a two-puncture procedure. In all instances the organism cultured was Staphylococcus epidermidis. All patients were seen in preterm labor. The presentation was characterized by malaise, myalgia, and a low-grade pyrexia beginning 5 to 10 days after the procedure. In all instances the women initially assumed they had acquired a viral illness. Although parenteral 1022 Weiner et al.

antibiotic therapy coupled with tocolysis was attempted in three instances, all infants were delivered prematurely. There were no deaths.

Preterm premature rupture of membranes within 7 days of the procedure occurred only after intravascular transfusion (N=3). Each patient was ≥ 34 weeks' gestation. There was no evidence of a learning curve for any of the practitioners in terms of the above complications.

The incidence of a clinically significant fetal brady-cardia (rate, <100 beats/min) was 6.6% (mean duration \pm SD, 6.6 \pm 8 minutes; range, 0.1 to 35 minutes). Thus the principal complication of accessing the fetal circulation for either diagnostic or therapeutic purposes was fetal bradycardia. All perinatal losses (and emergency deliveries) after a diagnostic procedure were directly the result of a prolonged procedure-related bradycardia (>15 minutes). In total, nine fetuses required emergency delivery, two with transfusion of either red blood cells or platelets when the umbilical artery was punctured, one because of hemolytic disease, and six because of early onset intrauterine growth retardation. Three of these fetuses had a chro-

mosome abnormality. The mean length of gestation at cesarean delivery of the karyotypically normal fetuses was 33 ± 3 weeks. None of these neonates were lost. Of the fetuses that experienced a bradycardiac episode that resolved without delivery, there were no apparent sequelae.

Two risk factors for bradycardia were identified (Table II). First, the incidence of bradycardia differed by the vessel punctured (umbilical artery, 21%; umbilical vein, 3.4%; p < 0.0001). There was no significant difference between diagnostic and therapeutic procedures in either the incidence of bradycardia or the resulting increase in the risk of bradycardia associated with arterial puncture. Fetuses who experienced bradycardia were similar in gestational age to those who did not.

Second, the incidence of bradycardia differed between appropriately grown and severely growthretarded fetuses, regardless of whether the artery or vein was punctured (Table II). No other diagnostic category (as defined in Table I) had an impact on the risk of bradycardia. In spite of similar ages, fetuses who experienced a procedure-related bradycardia had lower umbilical venous pH (7.38 \pm 0.05 vs 7.41 \pm 0.03; p < 0.0001), lower umbilical venous Po₂ $(32.6 \pm 16 \text{ vs } 38.3 \pm 8; p = 0.002)$, and higher umbilical venous Pco_2 (39.5 ± 6 vs 35.5 ± 4; p < 0.0001) than fetuses who did not experience a bradycardia. The umbilical artery systolic/diastolic ratio before the procedure was higher in fetuses in whom bradycardia developed (5.3 \pm 5 vs 3.9 \pm 3; p = 0.01). Of fetuses with absent umbilical artery diastolic flow, 21.4% had a procedure-related bradycardia, compared with 5.3% of those with any diastolic flow (p = 0.05). The incidence of arterial puncture was similar in both growthretarded and appropriately grown groups. Both growth-retarded and appropriately grown fetuses had a higher incidence of bradycardia when the umbilical artery was punctured.

Bradycardia was significantly more common after puncture of a midsegment than after puncture of the placental cord origin (10.8% vs 4%; p = 0.02). However, the likelihood of an arterial puncture also was significantly increased (19.8% vs 13.1%; p = 0.01). Fur-

p < 0.05, compared with appropriately grown fetuses.

^{||}p| < 0.002, compared with umbilical vein.

ther, growth retardation was disproportionately represented in the midsegment puncture group, no doubt because of the associated oligohydramnios. Therefore puncture of the midsegment itself did not appear a risk factor for bradycardia.

· On several occasions the umbilical artery was interrogated with pulsed Doppler during a bradycardiac episode. The vessel walls appeared thickened on realtime examination and either the systolic/diastolic ratio was increased over the preprocedure value or the diastolic flow was absent. As the heart rate began to normalize, diastolic flow returned.

There appeared to be a decrease in the incidence of fetal bradycardia when pancuronium was given (3.8% with pancuronium vs 7.9% without; p = 0.06, not significant). Unfortunately, the seemingly protective effect of pancuronium was confined to the group already at lowest risk for bradycadia—the appropriately grown fetus (6.0% without vs 1.5% with pancuronium, p < 0.03). There was no change in the incidence of bradycardia in severely growth-retarded fetuses after pancuronium (18.2% without vs 15.4% with pancuronium; p = 0.2, not significant). In addition, the effect of pancuronium did not vary with the vessel punctured. Almost all fetuses transfused received pancuronium, so that a similar evaluation of pancuronium for the therapeutic procedure group could not be done.

There were five procedure-related perinatal losses after a diagnostic procedure, yielding an uncorrected loss rate of 0.8% (5/594). Each of the five perinatal losses occurred in growth-retarded, hypoxemic, acidemic fetuses. Three of the five fetuses had a lethal trisomy, one had renal agenesis, and the fifth was severely growth retarded because of uteroplacental dysfunction with an estimated weight <500 gm at 29 weeks (460 gm at birth). In the latter instance the patient declined emergency cesarean delivery. Since none of these fetuses were likely to be salvageable, the corrected loss rate for diagnostic cordocentesis was 0%. The overall loss rate associated with intravascular transfusion was 3.6%. We have recently reported the results of fetal intravascular transfusion for the treatment of hemolytic disease in detail and will not duplicate it here.18 No fetus transfused because of a Coombs-negative anemia was lost. One additional appropriately grown fetus died 2.5 weeks after a diagnostic procedure and 3 days after an ultrasonographic examination had documented continued normal fetal growth. No evidence of either trauma, infection, or placental abnormality was observed at delivery shortly thereafter. The cause of the loss remains unknown, but we have not attributed it to the procedure. There were no other perinatal losses. Follow-up is 100%.

Comment

Whereas ultrasonographically guided percutaneous access to the fetal umbilical circulation has become common, factors contributing to losses and complications of the procedure remain largely unexplored. Our experience demonstrates that the risk of cordocentesis is highly influenced by the indication and the vessel punctured.

The major significant complication of cordocentesis was fetal bradycardia, leading either to perinatal death or to preterm delivery. Two independent risk factors for cordocentesis were identified, umbilical artery puncture and severe, early onset growth retardation.

The exact stimulus for the bradycardia is unknown. We have observed on several occasions a divergence in the systolic/diastolic ratio of the two umbilical arteries (including loss of diastolic flow in the punctured vessel) during the bradycardiac episode, which resolved as the heart rate returned to normal. This observation, coupled with the increased risk of bradycardia with arterial puncture, the increased echogenicity of the vessel during the episode, and the lack of an effect of uterine contractions on the umbilical artery systolic/diastolic ratio, suggests that the stimulus for the procedurerelated fetal bradycardia is localized arterial spasm at the site of puncture.

Severe, early onset growth retardation was an indepenent risk factor for bradycardia, because umbilical artery puncture occurred with equal frequency in growth-retarded and non-growth-retarded groups. There may well be a physiologic explanation for this observation. Hypoxia was most commonly observed in growth-retarded fetuses, and there was a relationship between bradycardia and suboptimal umbilical blood gas values. Arteries from various organs studied under hypoxic conditions in vitro have a tendency toward spontaneous contraction and an exaggerated response to catecholamines. We suggest that in vivo the umbilical arteries of hypoxic fetuses were similarly "twitchy." The observation that the systolic/diastolic ratio before the procedure was higher in fetuses who experienced bradycardia was consistent with our prior documentation of a relationship between the umbilical venous Po2 and an elevated systolic/diastolic ratio in potentially viable fetuses.11

Bleeding from the cord puncture site was not a clinically significant problem after any procedure in this series. However, significant fetal blood loss has been observed after cordocentesis.14, 15 Therefore it would be important to avoid factors associated with increased fetal blood loss whenever possible. Whether the lack of clinically significant bleeding in this series reflects a low number of indications associated with fetal hemorrhage (such as hemophilia and alloimmune thrombocytopenia), the method (freehand vs a needle guide), the needle size (22 gauge in our series vs 18 or 20 gauge), or the vessel punctured cannot be stated with certainty. However, eight fetuses with profound thrombocytopenia (<10,000 μl^s) were sampled without incident, and

the incidence and duration of bleeding from the puncture site of fetuses with a platelet count $<100,000/\mu l^3$ were unrelated to platelet number. We have not as yet tested a fetus with hemophilia or Glanzmann's thrombasthenia. Technique is a potential explanation for the absence of either a hemorrhagic or a thrombotic complication in this series. The percent of procedures complicated by a significant rise in the maternal serum α -fetoprotein concentration was greater after freehand intravascular transfusion.¹⁶ than after needle-guided intravascular transfusion.¹⁷ This suggests that lateral mobility permitted by a freehand technique increases the likelihood of trauma.

Since technique may have an impact on the complication rate, it is also appropriate to ask whether it could alter the overall loss rates. There are only two other large published series. Daffos et al. 6 (N=606) reported a 1.9% procedure-related loss rate and Boulot et al. 5 (N=322) a 3.1% loss rate. Each of these centers used a freehand technique. In spite of the fact that severe growth retardation was an uncommon indication for cordocentesis in either series, their combined loss rate was significantly greater ($\chi^2=4.0$, p=0.04) than the 0.8% uncorrected loss rate of this series.

Pancuronium seemed to protect against bradycardia by a mechanism that did not depend on the vessel punctured. There are several potential explanations that are not mutually exclusive. First, pancuronium increased the fetal heart rate. The fetal cardiac output has been reported to be essentially rate dependent. It may be that the vessel spasm induced by puncture was modest enough to be overcome by the increased blood flow. Second, intravenous pancuronium resulted in almost immediate paralysis of the fetus. Even small movement of the umbilical cord while the needle is in place could traumatize the smooth muscle and cause spasm. The latter explanation is supported by the observation that the protective effect of pancuronium did not vary with the vessel punctured.

We observed that the duration of bleeding from the umbilical cord varied with the vessel sampled. Arterial punctures bled longer, likely because of higher blood pressure. While the precise quantity of blood lost from the puncture wound cannot be estimated, it was not associated with a declining hematocrit after serial procedures. The increased duration of bleeding from the umbilical cord puncture site after transfusion may reflect either the development of a larger hole in association with the inevitable movement of the needle that must occur during any long procedure or dilution of platelet and soluble clotting components, as has been previously documented.¹⁹

Reports from the North American percutaneous umbilical blood sampling registry suggested that the longer a procedure took to complete, the greater the risk of

a complication, usually amnionitis.²⁰ The contributors to this registry all used a freehand technique. Time was not a relevant variable in this series. Either the vessel was punctured immediately or it was missed and the needle was removed. The incidence of amnionitis here was lower than that reported by other series.^{5, 6}

This series confirms that the umbilical vein is the target of choice for cordocentesis. Although in theory the umbilical artery might be preferred to the vein for the evaluation of growth retardation, the increased risk of bradycardia engendered by puncturing the artery outweighs, in our opinion, any potential benefit. The overall 83% success rate achieved for umbilical vein puncture demonstrates that the vessel punctured usually can be chosen and is not a chance event. However, in our experience vein puncture requires a willingness to target a midsegment when the umbilical arteries lie on top of the vein at the placental cord origin.

Because the risk of bradycardia varies with the indication, the consent form should be modified to reflect the indication. The risk of cordocentesis when the fetus is appropriately grown appears very low. When the fetus is severely growth retarded, the fetal weight should be estimated and the patient asked *before* the procedure to decide what should be done if a profound bradycardia results. We presently do not recommend cesarean section if the fetus is previable or has an estimated weight <500 gm.

There are instances, such as red blood cell alloimmunization or a fetal anomaly, where information obtainable with cordocentesis can be substituted by that obtainable with amniocentesis. In those circumstances it is appropriate to question whether the risks of cordocentesis outweigh its benefits. Clearly cordocentesis is more dangerous than amniocentesis. Bradycardia is not a major risk factor for amniocentesis. However, the risk and effects of bradycardia are probably the main difference between the two procedures. When a needle guide is used, the only difference between amniocentesis and cordocentesis is the target. Movement of the needle is essentially confined to the vertical plane. The other risks of needle puncture are the same regardless of the target. There are no modern series of latesecond-trimester to mid-third-trimester amniocentesis; however, our institution performs genetic amniocentesis with the same methods. The incidence of chorioamnionitis and rupture of membranes is virtually identical to that observed in this series. It is illogical to assume that the risks of premature rupture of membranes or chorioamnionitis are significantly less in the third trimester. We believe that if bradycardia is preventable, the risk of cordocentesis performed with a needle guide is the same as that with amniocentesis.

In summary, cordocentesis is a safe procedure. However, the risk does vary with both the vessel punctured and the state of fetal health. The loss rate experienced by a center will vary with the population composition. Further investigation of both the mechanism underlying fetal bradycardia and methods to prevent it are urgently needed.

Fetal blood sampling in patients undergoing elective cesarean section: A correlation with cord blood gas values obtained at delivery

Aldo D. Khoury, MD, Michael L. Moretti, MD, John R. Barton, MD, David C. Shaver, MD, and Baha M. Sibai, MD

Memphis, Tennessee

The purpose of this study was to compare blood gas parameters obtained after delivery and cord clamping with those obtained in the intact fetal circulation. Eighteen patients undergoing elective cesarean section at term were studied. Before the induction of epidural anesthesia, cordocentesis was performed under ultrasonographic guidance. Subsequently, a second sample was obtained for cord blood gas analysis after delivery. Umbilical venous blood was analyzed for pH, Po₂, Pco₂, and base excess. When comparing samples obtained from the intact fetal circulation with those obtained after delivery, there was a significant difference in pH (7.36 \pm 0.03 vs 7.31 \pm 0.04; p < 0.0001), Pco₂ (41.15 \pm 3.66 vs 46.29 \pm 5.71; p < 0.018), Po₂ (32.92 \pm 8.54 vs 26.97 \pm 4.43, p < 0.02), and base excess (-0.79 \pm 1.19 vs -2.36 \pm 1.48; p < 0.0003). These results should be considered when cord blood gas values obtained at delivery are correlated with those from the prenatal fetal state. Blood gas values obtained at delivery may not reflect the true prenatal fetal acid-base status. (AM J OBSTET GYNECOL 1991;165:1026-9.)

Key words: Cordocentesis, fetal blood gases, delivery cord blood gases.

bilical cord blood gas measurements in all deliveries. The presence of umbilical cord acidemia in the vigorous newborn did not correlate well with neonatal outcome. In their study, 3% of newborns with an umbilical venous pH <7.20 had normal Apgar scores. The cause of acidemia in these vigorous newborns remains speculative.5,6 It may be maternal in origin, as a result of increasing acidosis in the mother as labor progresses, and thus not reflecting true fetal acid-base status.

The introduction of cordocentesis has made it possible to safely study fetal acid-base status in the intact circulation. The use of cordocentesis for fetal blood sampling removes many of the confounding variables that may affect cord blood gas values, such as labor uterine manipulation, anesthesia, and expulsive forces of the mother. The purpose of this study was to compare umbilical blood gas values obtained at cordocentesis with those obtained at delivery and cord clamping.

Material and methods

The study group included 18 healthy pregnant women at term requiring elective cesarean section. Entry criteria included singleton pregnancy, ≥38 weeks' gestation, intact fetal membranes, absent medical or obstetric risk factors, reactive nonstress test before the procedure, and no evidence of labor. All fetuses were structurally normal with appropriate growth. All patients received and signed consent forms previously approved by the investigational review board. Patients were admitted to the labor and delivery suite in the morning, and external fetal monitoring was performed. After absence of uterine contractions and a

reactive heart rate tracing with no abnormalities were documented, each patient was transferred to the operating room and placed in the left lateral decubitus position. An epidural catheter was inserted; however, no medications were introduced into the catheter. A fluid preload of 1000 ml lactated Ringer's solution was administered before initiation of epidural blockade; after blockade was achieved none of the patients had hypotension necessitating treatment with ephedrine or any other vasopressor. Supplemental oxygen was not used until the infant was delivered and cord gases were obtained. Because of the inherent delay from cordocentesis to delivery, the fetal heart was continuously monitored throughout this period, as was maternal blood pressure at 5-minute intervals. The patient was then prepped and draped in the usual sterile fashion for a cesarean section, and cordocentesis was performed by direct ultrasonographic guidance prior to administration of the epidural block.

A 5 MHZ sector transducer was used (ATL Ultramark 5) to locate the placental origin of the umbilical cord when possible; otherwise a free loop of cord was selected. A 5- or 6-inch 22-gauge spinal needle was inserted and guided into the selected portion of the cord. After ultrasonographic confirmation that the umbilical cord was entered, 1 ml blood was collected into prepackaged, preheparinized syringes. Umbilical venous pH and gas measurements were performed within 15 minutes of collection. An additional 3 ml blood was collected into a nonheparinized syringe, and a portion was sent for Kleihauer-Betke smear, to confirm the fetal origin of the sample. The needle was removed and the fetal heart rate was observed for 10 minutes, as was the puncture site, to detect any bleeding or abnormal fetal heart tracing.

The patient was then placed supine with left lateral uterine displacement, and a repeat cesarean section was performed. Within 30 seconds of delivery a segment of umbilical cord was clamped at both ends and venous blood collected into 1 ml heparinized syringes. Blood pH, PO₂, PCO₂, and base excess were immediately measured after the blood sample was collected. The blood gas analyzer used was the Instrumentation Laboratory System 1301 analyzer. The margin of error for the blood gas parameters included pH, 0.01; Pco₂, 1.5; and Po₂, 2.

Neonatal outcome included gestational age, birth weight, and Apgar scores at 1 and 5 minutes. The results of blood gases were compared with Student t test. A p value < 0.05 was considered significant.

Results

There were no cases of fetal bradycardia or fetal heart rate decelerations during or after cordocentesis. The mean \pm SD of observed blood streaming from the umbilical cord was 24 ± 20 seconds (range, 20 to 70 seconds). Fetal blood was documented by Kleihauer-Betke smear in all cases. Seventeen patients underwent epidural anesthesia, and one had general anesthesia because of failed epidural anesthesia. Because of the different mode of anesthesia, this patient was not included in the analysis. There was no significant difference in blood pressure before and after initiation of epidural anesthesia (mean systolic, 130 vs 122 mm Hg; mean diastolic, 82 vs 78 mm Hg). None of the patients had a reduction in either systolic or diastolic blood pressure ≥18 mm Hg. The mean ± SD interval from cordocentesis to delivery was 22.6 ± 2.3 minutes (range, 18 to 30 minutes). Table I compares the blood gas findings at cordocentesis with those at the time of delivery in the 17 patients receiving epidural anesthesia. There were significant differences in all parameters studied between cordocentesis values and delivery cord values. The data were subsequently analyzed according to whether the systolic blood pressure after epidural anesthesia decreased by <10 or ≥ 10 mm Hg. In the group of patients where the change in the systolic blood pressure was <10 mm Hg (n=10), the mean \pm SD of cord pH predelivery was 7.36 ± 0.04 and after delivery was 7.32 ± 0.03 (p < 0.009, by paired t test). In the group of patients where the change in the systolic blood pressure was ≥ 10 mm Hg (n = 7), the mean \pm SD of cord pH predelivery was 7.36 ± 0.03 and after delivery was 7.30 ± 0.04 (p < 0.025, by paired t test). Thus the magnitude of change of the systolic blood pressure did not affect the results of pH values.

All infants were structurally normal and had a birth weight >25th percentile for gestational age. The mean \pm SD for gestational age was 39.6 \pm 0.76 weeks (range, 38.0 to 40.5), for birth weight it was 3419 \pm 467 gm (range, 2900 to 3870). The mean \pm SD Apgar scores were 8.2 \pm 1.0 (range, 6 to 9) and 8.6 \pm 1.4 (range, 7 to 9) for 1 and 5 minutes, respectively.

Comment

With the development of fetal blood sampling by cordocentesis, we are afforded the opportunity to study the fetal acid-base status in the intact fetal circulation. There is a paucity of data on normal blood gas parameters in the term fetus before labor. Previous studies with cordocentesis have provided reference ranges for fetal blood gas parameters. The However, the patient population in these studies came from a high-risk referral group in which the suspected pathologic condition was ruled out by the fetal blood sampling; thus this may not truly represent a normal control group. In addition, there were few patients included with a gestational age >38 weeks.

Unlike previous reports, this study is unique in that it comprised a homogeneous group of patients, devoid of perinatal risk factors and without signs of fetal growth failure. To our knowledge, this is the first report comparing umbilical venous delivery pH in an experimentally controlled fashion with the actual in utero fetal acid-base status. This was possible because we studied healthy pregnant women at term who required elective cesaran section before the onset of labor. Consequently, many of the confounding variables that might affect cord blood gas values were removed, and the interval from fetal sampling to delivery was thus shortened. Although there was still a considerable interval period, it should be noted that the fetal heart and maternal blood pressure were monitored continuously during this period, and no significant changes were noted that may have influenced the results.

The results of this study reveal a significant difference in blood gas values at cordocentesis to those at delivery. The pH and Po2 of the cord blood at delivery were significantly lower than those obtained from fetal blood, whereas the Pco₂ and base excess were consistently higher. These findings may have important implications when relating umbilical cord blood gas results obtained at delivery to the actual prenatal fetal acid base status, and when using these cord blood gas parameters as an end point for evaluating methods of antepartum surveillance. None of the fetuses or neonates studied in this report had evidence of acidosis; however, it is important to note that the average difference in pH values between the two samples was 0.04 units (range, 0.02 to 0.15). This exceeds the margin of error reported for the blood gas analyzer used. Thus it is conceivable that in certain clinical situations an acidotic pH may be present on cord blood at delivery when in fact the fetus is not in an acidotic state.

Most infants with acidosis at birth appear to be in a vigorous or intermediate condition, which raises the possibility that such acidosis is not entirely fetal in origin. Indeed, other authors have postulated that there is movement of hydrogen ions and lactate across the placenta from mother to fetus. Maternal acidosis that takes place during the second stage of labor is to some extent due to the expulsive and ventilatory efforts by the laboring patient during uterine contraction. Consequently, this may result in a downward trend in fetal pH, showing increasing steepness as delivery approaches, due to this net movement of hydrogen ions from mother to fetus.9-18 In addition, the cord blood gas values may be influenced by factors that involve interruption of the uteroplacental circulation at delivery, as well as in the actual collection of the sample for analysis.14

In summary, the acid-base status of the fetus as determined by cord blood gas analysis may not accurately reflect the true acid-base status of the fetus in utero. This may help explain the reported discrepancy between acidosis detected at delivery and neonatal outcome.5,6 These differences in blood gas parameters obtained in utero as compared with those obtained at delivery are most likely related to variables surrounding the delivery process and to techniques of collection and processing of blood samples. However, a larger number of patients will be helpful to ascertain these differences. Finally, the blood gas parameters found at time of cordocentesis in this study may be used as a reference range for the normal term fetus.

Amniotic fluid bilirubin and fetal hemolytic disease

Joseph A. Spinnato, MD, Kathleen K. Ralston, MT (ASCP), Eileen R. Greenwell, MT (ASCP), Carolyn A. Marcell, RN, and Joseph A. Spinnato III, BS Louisville, Kentucky

Six different methods for assessing amniotic fluid bilirubin were compared in 111 samples from 37 patients. When the Liley methods were compared, the chloroform extraction and 5% correction methods resulted in 20% and 4% reductions, respectively, in the mean change in optical density at 450 nm when compared with the uncorrected mean $(0.086 \pm 0.06 \ [p < 0.05])$ and $0.104 \pm 0.07 \ [p]$, not significantly vs 0.108 ± 0.08). This reduction was observed in spite of significant visual blood contamination being rarely noted. The predictions based on amniotic fluid analysis were compared with the first fetal or neonatal hematocrit. The chloroform-extracted change in optical density at 450 nm accurately predicted fetal status in all patients, whereas lesser degrees of accuracy were observed with other methods. Hydrops fetalis did not occur during the observation period, and fetuses needing transfusion (n = 5) or early delivery (n = 10) were indicated correctly. The chloroform extraction change in optical density at 450 nm accurately predicts fetal status, and its use should continue. (Am J Obstet Gynecol 1991;165:1030-5.)

Key words: Amniotic fluid bilirubin, fetal hemolytic disease

In 1961, to evaluate the severity of fetal hemolytic disease, Liley introduced a technique of amniotic fluid bilirubin analysis that revolutionized the care of patients at risk. The results reported in that article suggested that the severity of hemolytic disease could be predicted by considering the size and trend of the 450 nm spectrophotometric peak in amniotic fluid in relation to the three zones of classification described. Extra caution was recommended to prevent overestimation of the severity of hemolysis when contaminants, such as oxyhemoglobin, were present in the fluid. A technique for the correction of the change in optical density (OD) at 450 nm (ΔOD₄₅₀) (the 5% method) also was described.

In 1986 Nicolaides et al.² assessed amniotic fluid specimens (N = 475) from unaffected fetuses of 16 to 36 weeks' gestation. No method for evaluating or correcting for the presence of oxyhemoglobin was described. A large proportion of values fell into the middle zone of the Liley graph rather than into the unaffected low zone. Among 59 sensitized patients, 25% of whose fetuses were hydropic at the time of sampling, the predictive value of the ΔOD_{450} was determined to be limited. Fetal blood sampling was performed on patients at risk. The authors concluded that the only reliable method for determining the severity of rhesus

isoimmunization in the second trimester of pregnancy is the direct measurement of fetal hemoglobin.

The implications of this study's conclusions are enormous. Routine fetal blood sampling of sensitized patients in the second trimester is endorsed. Before such a recommendation can be adopted, careful consideration must be given to the accuracy of the assessment of the Liley technique, the increased technical difficulty and risk of umbilical vein sampling, the lack of widespread availability of the technique, and the potential of routine sampling for worsening the fetal sensitization. These concerns prompted our investigation.

The hypothesis of our study is that the properly performed and carefully interpreted, corrected ΔOD_{450} , assessed for both size and trend of value, will accurately predict the severity of fetal hemolytic disease. Further, if this is so determined, continued use of amniocentesis and ΔOD_{450} offers advantages over routine fetal blood sampling.

Material and methods

The Perinatal Laboratory of the University of Louis-ville Department of Obstetrics and Gynecology is a regional referral site for amniotic fluid analysis. Amniotic fluid specimens from patients at risk for hemolytic disease in the fetus were obtained, largely from ultrasonographically directed amniocentesis performed in our obstetric ultrasonography center. Those specimens were processed immediately. Fluids received from other facilities were sent chilled and light protected.

The specimens were placed in a centrifuge (GCA/Precision Scientific, Chicago) at 1000g for 5 minutes to remove red cells and other debris, and the supernatant was filtered through Whatman No. 4 filter

paper (Whatman International Ltd., Maidstone, England). After centrifugation, the pellet and supernatant were visually inspected for blood or meconium contamination with a continuous recording spectrophotometer (Milton Roy Spectronic 1201, Milton Roy Company, Rochester, N.Y.) with a 1 cm light path quartz cuvette. An aqueous solution of 8-hydroxyquinoline was used as a quality control solution. Specimens with visual evidence of high concentrations of bilirubin were diluted as necessary. Six different methods of bilirubin analysis were performed.

Liley ΔOD_{450} . The specimens were scanned between the wavelengths of 350 and 600 nm on a linear scale against a water blank. Individual readings were taken at 550, 450, and 365 nm. These values were transferred to a semilogarithmic scale, and a straight line was drawn between 550 and 350 nm. The difference between the straight line and the individual point reading at 450 nm, the Liley ΔOD_{450} , was plotted on a Liley graph to assess the severity of hemolysis.1

Chloroform-extraction Liley ΔOD_{450} . Four milliliters of chloroform (Spectranalyzed; Fisher Scientific, Springfield, N.J.) were added to an equal volume of centrifuged amniotic fluid. The mixture was held on a vortex mixer (Vortex Genie 2, Fisher Scientific, Springfield, N.J.) for 30 seconds and placed in a -18° C freezer (White Westinghouse, Dublin, Ohio) for 5 minutes. It was centrifuged for 5 minutes at 1000g, and the bottom chloroform layer was scanned in a recording spectrophotometer. A chloroform blank was used in this procedure.3 The remainder of the analysis was identical to the standard Liley technique.

Five percent corrected Liley ΔOD_{450} . The ΔOD_{410} (oxyhemoglobin peak) was determined by calculating the difference between the straight line (drawn from 375 to 525 nm) at 410 nm and the individual reading at 410 nm. Five percent of this value was calculated, subtracted from the original Liley ΔOD₄₅₀ to produce the corrected $\Delta \mathrm{OD}_{450}$, and plotted and interpreted as 'with the other Liley techniques.'

Queenan ΔOD_{450} . The amniotic fluid samples were scanned between the wavelengths of 350 and 600 nm, recording the absorbance against the wavelengths on a linear scale. A water blank was used to zero the instrument. A straight line was drawn from 375 to 525 nm, demonstrating the approximate course of the amniotic fluid scan in the absence of bilirubin pigments. The difference between the straight line and the graph at 450 nm is the ΔOD_{450} and is linearly proportional to the concentration of bilirubin. The value obtained was plotted on Queenan's prediction graph to indicate the severity of disease.4

Queenan corrected ΔOD_{450} . The absorbance of the curve at 575 nm was subtracted from the absorbance of the curve at 455 nm. Since the alteration of the curve due to the absorbance of oxyhemoglobin at 575 nm is

thought to be essentially the same as that at 455 nm, subtracting corrects for contamination. This value was plotted on Queenan's corrected prediction graph to assess severity of disease.4

Percent transmittance. Centrifuged and filtered amniotic fluid was evaluated with a recording spectrophotometer. The percent transmittance reading at 520 nm was divided by the percent transmittance at 490 nm against a distilled water blank. The resulting value is the percent transmittance ratio.5 The fetus was considered at risk with the following values: percent transmittance ratio ≥ 1.25 before 30 weeks' or a ratio ≥ 1.15 after 30 weeks' gestation.6

The three Liley $\Delta \mathrm{OD}_{450}$ measurements were generally interpreted as previously suggested.^{1, 7} However, consistent with our clinical experience, all management recommendations were based on the chloroform extraction ΔOD_{450} method. Values in the lower zone and the lower one third of the middle zone were considered reassuring, and repeat evaluation was performed within 3 to 4 weeks. Values in the upper zone or in the upper one third of the middle zone were considered ominous and prompted umbilical vein sampling or delivery if pulmonary maturity was demonstrated. Selected patients with values in the upper one third of the middle zone were reassessed by bilirubin analysis within 7 to 10 days. Values in the middle third of the middle zone prompted repeat amniocentesis within 2 weeks. A declining trend was considered reassuring. A level or rising trend was interpreted as possible fetal jeopardy. However, umbilical vein sampling was not performed until the $\Delta \mathrm{OD}_{450}$ was at, or exceeded, the upper third of the middle zone.

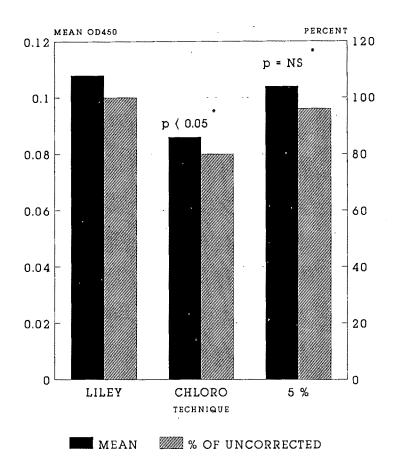

The Queenan values were considered reassuring if in the lower zone, ominous if in the upper zone, and requiring trend analysis if within the area of overlap.4 The percent transmittance ratio was considered reassuring or nonreassuring as described above.

The following outcome parameters were evaluated: (1) estimated gestational age at delivery, (2) first umbilical vein hematocrit at delivery or percutaneous sampling, (3) neonatal direct 'Coombs' test values, and (4) neonatal length of hospitalization. The accuracy of each method of bilirubin analysis was determined for each patient. The results were categorized as accurate, accurate but requiring trend analysis, or inaccurate (misleading).

Differences among the means were analyzed by analysis of variance. Differences between group means were evaluated by the least significant difference t test. Significance was set at p = 0.05.

Results

From June 1988 through June 1990, 111 amniotic fluid specimens were obtained from 37 patients (3.0 samples per patient; range I to 6). Forty-four speci-

103 SAMPLES; * versus uncorrected mean

Fig. 1. Mean ΔOD₄₅₀ among three Liley techniques, uncorrected (*LILEY*), chloroform extraction (*CHLORO*), and 5%. For each method percent of uncorrected mean is represented. NS, Not significant.

mens were obtained from patients at or before 29 weeks' gestation. Nineteen patients were antibody positive for the Rho(D) antigen (either alone or in combination). The remaining patients were sensitized to single or multiple atypical antigens. The mean gestational age at amniocentesis was 29.5 weeks (range 21 to 39 weeks).

Inspection of the spectrophotometric curve at 410 nm (oxyhemoglobin peak) demonstrated a measurable, positive deviation from expected for 86 of 111 (77%) samples, resulting in a downward correction of the $\Delta \mathrm{OD_{450}}$ (5% correction method) for these samples. Similarly, the chloroform extraction method resulted in a decrease of the $\Delta \mathrm{OD_{450}}$ in 93 of 103 (90%) specimens. These corrections were found in spite of visually noting only 32% (35/111) of specimens were contaminated by blood and finding, of those, only 66% (23/35) with trace evidence of blood (<1%) in the centrifuged pellet. Meconium and concentrated bilirubin were each noted in only one specimen.

Among ΔOD_{450} values in which all three Liley methods were assessed (n=103), the chloroform extraction

and 5% correction methods, respectively, resulted in a 20% (0.086 \pm 0.06; p < 0.05) and 4% (0.104 \pm 0.07; p, not significant) reduction in the mean ΔOD_{450} when compared with the uncorrected value (0.108 \pm 0.08) (Fig. 1).

There were no known perinatal losses. Hydrops fetalis did not occur. Umbilical vein sampling was required in only five of 37 patients (14%). Two fetal hematocrits were <15% (9% and 13%) without evidence of hydrops. In both cases the first amniocentesis and umbilical vein sampling were performed immediately on entry into care. The other three first fetal hematocrits were 17.3%, 17.5%, and 34.5%. The neonatal findings of the 25 patients whose infants were noted to have a positive direct Coombs' test are summarized in Table I. Of the remaining 12 patients, one underwent intraperitoneal transfusion and fetal hematocrit was not available, three neonates were known to be direct Coombs' negative, six were noted to have low-zone ΔOD₁₅₀ values at 34 to 37 weeks' gestation and specific follow-up was not obtained, and two patients were lost to follow-up. Unexpected severe disease, as measured

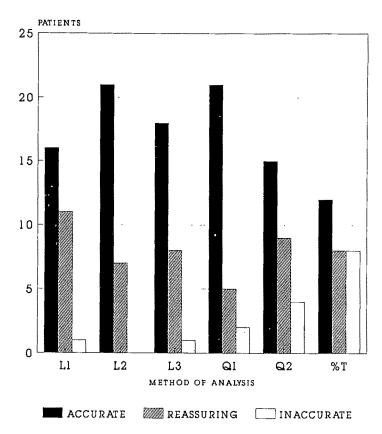

Fig. 2. Comparative accuracy of each method, uncorrected Liley (L1), chloroform extraction (L2), 5% corrected (L3), Queenan (Q1), corrected Queenan (Q2), and percent transmittance (%T), among 28 patients with known outcomes. Designation of "accurate" was given if each individual amniotic fluid value correctly identified fetal status. "Reassuring trend" was assigned if declining trend of values (two or more amniocenteses) was apparent. "Inaccurate" was assigned if method was inappropriately reassuring or alarming.

by first hematocrit, was not observed. The first hematocrit ranged from 33% to 66% among newborns who did not receive fetal transfusion.

The predictions of the six methods of bilirubin analysis used in the 28 patients with known outcomes are summarized in Fig. 2. The chloroform-extracted ΔOD₄₅₀ correctly identified fetal status at each sampling performed in 21 of 28 patients. The remaining seven patients had results in the middle third of the middle zone but had a downward trend (reassuring) in each case (Fig. 3). Four of these patients' values dropped into the lower zone at third-trimester sampling. Thus trend analysis was required more frequently in the second trimester. No patient was inaccurately categorized. Four of the five fetuses who underwent umbilical vein sampling were noted to have hematocrits of <20% without evidence of hydrops fetalis. If used for clinical management, each of the other techniques would have either required more trend analysis for reassurance or prompted unnecessary fetal blood sampling. Queenan's uncorrected method performed nearly as well as the chloroform extraction technique. The 5% method

^{*}Excluding transfused fetuses (n = 20).

did not reduce the ΔOD₄₅₀ as much as the chloroform extraction technique and resulted in more samples falling in the middle of the middle zone, prompting more frequent amniocentesis if used clinically. The percent transmittance technique did not discriminate accurately enough between fetuses requiring or not requiring blood sampling. In other words, when compared with the other techniques, the chloroform extraction tech-

October 1991 Am J Obstet Gynecol

nique allowed a more accurate interpretation of fetal status and permitted less frequent amniocentesis.

Comment

The findings of this study are noteworthy for several reasons. The influence of amniotic fluid contamination by blood, from either a maternal or fetal source, may be greater than previously appreciated. Although visual evidence of trace or greater contamination was noted in 32% of the centrifuged pellets of amniotic fluid specimens, direct evaluation of the curve by the 5% method resulted in a reduction of the ΔOD_{450} for 77% of samples by an average of 4%. More striking was a 20% reduction of the mean $\Delta \mathrm{OD}_{450}$ by the chloroform extraction technique. This percent reduction is similar to the results reported originally.3 Perhaps visual inspection alone is inadequate to decide whether correction is necessary. We can only speculate why there is such a substantial difference between the correction techniques. The 5% correction of Liley' may merely undercorrect the value. The original description suggests the method was based on experimental contamination; however, no details of the findings were given. The chloroform extraction technique has been noted to successfully recover all bilirubin when compared with preextraction values,3 so artifactual lowering of the bilirubin content seems unlikely.

Our patient management was based entirely on the chloroform extraction ΔOD_{450} method. Patients required an average of three amniocenteses. There were no fetal deaths, and hydrops fetalis did not occur under our supervision, despite infrequent use of umbilical vein sampling. There were no surprise severe anemias. Among fetuses thought to have severe anemia who underwent blood sampling, four of five were severely anemic and were at or near values associated with hydrops fetalis. While hydrops did not occur, sampling was not performed until bilirubin values were in the upper zone of Liley's graph (two were at first amniocentesis). As a consequence, we have become more aggressive when high or rising midzone values are noted. Only one first fetal umbilical vein hematocrit (34.5%) was above that which prompts fetal transfusion.

Nicolaides et al.² noted that most ΔOD₄₅₀ values among the 475 samples collected from nonsensitized patients fell in the middle zone of the Liley extended graph. The graph used in that study is an arbitrary, not data-based, extension of Liley's original graph.⁸ No correction technique was identified as having been performed on the samples. From visual inspection of data points, it would appear that many, if not most, of the values would have been relocated in the low zone or in the lower third of the middle zone if an average 20% correction had been applied to the noted values. Thus

most of the values would fall in a reassuring range. Few details regarding these patients were reported; therefore the conditions that prompted sampling (viral disease, fetal anomaly) possibly could have altered amniotic bilirubin, independent of red blood cell sensitization.

In the above-mentioned report,2 the authors assessed the interpretability of the uncorrected ΔOD_{450} method among sensitized patients. Included in the patient sample were 25 (of 59) patients whose fetuses were hydropic at the time of sampling. We believe it is inappropriate to include such patients in this analysis. Most clinicians would consider an amniocentesis unnecessary when hydrops had been noted. In such cases it is possible that fetal anemia may be so profound that amniotic fluid bilirubin is lowered because of lack of substrate (fetal red blood cells). In addition, associated polyhydramnios may exert a diluting effect on optical density. In spite of this, we noted that only one of the 25 hydropic fetuses (no details given) had a ΔOD₄₅₀ value below the middle of the middle zone. Further, the authors did not attempt to evaluate the trend of serial samples but merely judged the individual values. Trend analysis, as first emphasized by Liley,1 is necessary to properly interpret values in the middle zone. We needed to use trend analysis for seven of the 28 patients in this study; its use safely and successfully avoided unnecessary umbilical vein sampling. Trend analysis may be required more frequently in the second trimester. However, this may be the consequence of an inaccuracy in the arbitrary extension of the Liley graph. A data-based modification of the extended Liley graph using chloroform-extracted values is probably warranted. However, because of uncertainty regarding the technique used and patients enrolled in the study of Nicolaides et al.,2 we believe his data may not suit this purpose.

Nicolaides et al.² have concluded that the only reliable method for second-trimester evaluation of patients at risk is the direct measurement of fetal hemoglobin. We argue that our experience supports the continued use of amniotic fluid analysis in the second trimester. Their assessment of amniotic fluid analysis by the Liley method is flawed by a failure to correct for fluid contamination, inclusion of hydropic infants in the analysis, failure to judge trend analysis, and no assessment of the risk/benefit ratio for routine fetal blood sampling versus amniotic fluid analysis. A consensus estimate of fetal loss from umbilical vein sampling, although difficult to extract from the literature, is probably 1% to 2%.9. 10 Umbilical vein sampling, particularly when transplacental, may worsen the severity of sensitization as much as, if not more than, amniocentesis. The appropriate interval between blood sampling episodes has not been adequately studied. Does a fetal hematocrit

of 33% prompt reevaluation in 2 or 3 or 4 weeks? Will routine second-trimester blood sampling, if used, interfere with third-trimester amniotic fluid analysis? Will pregnancy outcome be improved by this more hazardous technique? The authors offer no real comparative data on which they base their conclusion.

The American College of Obstetricians and Gynecologists, apparently in response to the article by Nicolaides et al.,2 has revised its technical bulletin11 regarding isoimmunization. In the October 1990 bulletin, the Liley graph is presented without the second-trimester extension previously endorsed in the January 1986 bulletin.8 Fetal blood sampling is recommended for most patients at risk first seen in the second trimester. The willingness of the American College of Obstetricians and Gynecologists to change its recommendations on the basis, in large part it would appear, of this one report is surprising.

For now, an endorsement of routine fetal blood sampling to assess patients at risk is premature and inadvisable. Properly performed and interpreted amniotic fluid bilirubin analysis by the chloroform extraction technique permits accurate fetal assessment, thereby in most cases (86% in our series) avoiding fetal blood sampling.

We thank Ms. Maggie Steptoe and Ms. Robin Newlon for editorial assistance and manuscript preparation.

What is a low-lying placenta?

Lawrence W. Oppenheimer, MD, Dan Farine, MD, J.W. Knox Ritchie, MD, Reuven M. Lewinsky, MD, Joyce Telford, RN, and Lea A. Fairbanks, MD

Toronto, Ontario, Canada

Transvaginal ultrasonography was performed in 127 women thought to have placenta previa. In all cases of complete previa, placental location was confirmed at cesarean section. Where the placenta was situated in the lower segment of the uterus but did not cover the cervical os the distance from the placental edge to the internal cervical os was measured. This distance was analyzed in relation to the route of delivery. No patient with a placental edge >2 cm from the internal cervical os required cesarean section for the indication of placenta previa, whereas seven of eight patients with a distance of ≤2 cm underwent cesarean section because of bleeding characteristic of a placenta previa. These preliminary results suggest that transvaginal ultrasonography measurement may indicate the optimal delivery route and make the traditional classification of placenta previa obsolete. (AM J OBSTET GYNECOL 1991;165:1036-8.)

Key words: Placenta previa, transvaginal ultrasonography, cesarean section

The classification of placenta previa into complete, partial, marginal, and low-lying was originally based on digital palpation of the placenta through the cervical os1 and has remained unchanged in spite of the advent of modern obstetric care and the widespread use of ultrasonography for the diagnosis of placenta previa.2 This is at least in part because the standard method of transabdominal ultrasonography is often insufficiently precise in determining the exact relationship of the placental edge to the internal cervical os.⁸ The greater resolution of transvaginal ultrasonography enables accurate visualization of the internal os.4 Transvaginal ultrasonography has been shown to be a safe technique in placenta previa and to be superior to transabdominal ultrasonography in the prediction of placental location at delivery.⁵⁻⁷ Where the placental edge encroaches on the os, the intervening distance can be measured at transvaginal ultrasonography. In this study we retrospectively examined the role of a classification of placenta previa with the use of transvaginal ultrasonographic measurement in predicting the route of delivery.

Material and methods

One hundred twenty-seven women with antepartum hemorrhage or with previous transabdominal ultrasonography suggestive of placenta previa were referred for further ultrasonographic evaluation. All patients

underwent transabdominal ultrasonography and transvaginal ultrasonography. Transvaginal ultrasonography was performed with the use of a 5.5 MHz vaginal probe (Acuson, Mountain View, Calif.) after the patient voided. Placenta previa was defined as any placental tissue visible in the lower segment of the uterus at transvaginal ultrasonography. A complete previa was diagnosed if placental tissue extended over the internal cervical os. Where a placental edge was visible on transvaginal ultrasonography but did not cross the internal os, the intervening distance was measured in centimeters by a minimum of two operators (Fig. 1) and a mean value was calculated. Only the results of ultrasonographic scans performed in the third trimester were included in the study, and where ultrasonography had been repeated, the most recent studies were analyzed. The outcome measure was route of delivery, with verification of placental location if delivery was by cesarean section. All ultrasonographic results were available to the physicians, who made the decision to perform cesarean section on the basis of the presence of significant bleeding.

Statistical significance was calculated with the unpaired t test.

Results

Transvaginal ultrasonography was performed in 127 patients at an average gestational age of 33 ± 4 weeks (mean \pm SD) and delivery occurred at 38 ± 3 weeks. Of the 127 patients, 52 were diagnosed as having placenta previa. The internal cervical os was visualized at transvaginal ultrasonography in all cases. Thirty-one patients had complete previa, and the placental location was confirmed at subsequent cesarean section in all these cases. In the remaining 21 cases the outcome variable of mode of delivery was correlated with the

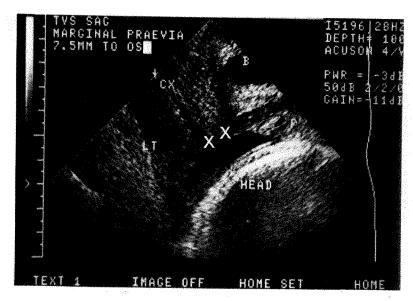

Fig. 1. Transvaginal ultrasonographic scan at 34 weeks' gestation. Cervical canal is clearly visible (CX) and distance from internal os to placental edge, measured between calipers (X), is 0.75 cm. The patient was delivered by cesarean section 4 weeks later because of vaginal bleeding. P, Placenta; B. bladder.

transvaginal ultrasonographic distance from the placental edge to the internal os. In 7 of these 21 patients who required a cesarean delivery because of bleeding, the mean distance was 1.1 ± 0.8 cm (range, 0 to 2 cm), compared with a distance of 3.1 ± 1.1 cm (range, 1.8to 5.8 cm) in the remaining 14 patients who did not require a cesarean section because of placenta previa (p = 0.0004). Four patients in the latter group underwent cesarean section for other reasons and 10 were delivered vaginally. The differences in the distances from the placental edge to the internal os between these two groups were statistically significant (p = 0.0004).

Only one patient with a placental edge within 2 cm of the cervical os was delivered vaginally. In this case transvaginal ultrasonography had been performed at 28 weeks, and delivery occurred 11 weeks later.

There were three cases in this series in which a "double setup" examination was performed. In two of these the placental edge was within 2 cm of the cervical os by transvaginal ultrasonography and cesarean section was performed. In the third case the placental edge lay 5.5 cm away and the patient was delivered vaginally.

Comment

The terminology of the traditional classification of placenta previa was derived from digital palpation of the placenta through a partly dilated cervix in labor. There is little debate about the diagnosis and management of a complete previa in late pregnancy, but the terms partial and marginal placenta previa are not applicable to the antenatal ultrasonographic appearance of the cervix, which is visualized as a discrete point.8.9

Similarly, the concept of the low-lying placenta provides little information about its clinical significance. In those cases where the placenta does not cover the os antenatally, what is really required from ultrasonography is a prediction of the likely clinical course and mode of delivery, on the basis of actual distance between the placental edge and the internal cervical os.

A change in the relative position of the placenta, or placental migration, can occur in the third trimester, 10 and this may explain the one case in our series with a placental edge within 2 cm of the os in which vaginal delivery occurred. It is now our practice to perform transvaginal ultrasonography every 4 weeks in such cases to document migration. In the three cases where double setup examination was performed, the transvaginal ultrasonographic distance from the placental edge to the internal os would have predicted whether the placenta would be palpable on digital examination. Therefore transvaginal ultrasonography could replace the requirement for the double setup examination.

It is possible that the transvaginal ultrasonographic result itself influenced management decisions; however, we suggest that the greater accuracy of transvaginal ultrasonography in excluding complete previa encouraged the physician to manage these cases expectantly. There is no absolute gold standard for the diagnosis of placenta previa, and whereas successful vaginal delivery excludes clinically significant previa, the performance of a cesarean section does not prove that vaginal delivery could not have occurred. Although the outcome measure used in this study is not an absolute one, it does reflect a prevailing clinical standard with which to compare the ultrasonographic results.

In conclusion, we have shown that a transvaginal ultrasonographic measurement of placental edge to internal os of >2 cm reliably predicted safe vaginal delivery. A shorter distance was often associated with bleeding necessitating cesarean section. However, further studies are necessary to validate this value as a useful cutoff point. Furthermore, we suggest that the advent of high-resolution transvaginal ultrasonography makes the traditional classification of placenta previa obsolete.

Pulmonary-to-aorta diameter ratio in the normal and abnormal fetal heart

Christine H. Comstock, MD,^a Thomas Riggs, MD,^b Wesley Lee, MD,^a and Janet Kirk, MD^a Royal Oak, Michigan

In an attempt to establish the normal ratio of pulmonary artery to aorta diameters at varying gestational ages, the pulmonary artery and aorta diameters of 316 normally grown fetuses between 14 and 39 weeks' gestational age were measured. The ratios for each fetus were derived, and regression analysis was used to evaluate the relationship between gestational age and each diameter. We conclude that the diameters of the pulmonary artery and aorta are closely related to fetal age but that the ratio is independent of age (mean, 1.09; SD, 0.17). The diameters of the pulmonary artery and aorta in 21 fetuses with proved congenital heart disease were then compared with those of this normal population. The pulmonary artery/aorta ratio was abnormal in 13 of 21 fetuses with congenital heart disease. Actual measurements of the great vessels can be difficult and may be misleading, but a quick comparison of relative size by inspection is feasible. (AM J OBSTET GYNECOL 1991;165:1038-44.)

6/6/31429

The current screening view of the fetal heart is the four-chamber view. However, this view does not detect abnormalities involving the great vessels, such as truncus arteriosus, transposition, or double-outlet right ventricle, nor does it always detect tetralogy of Fallot. As examiners become more experienced, the screening examination will undoubtedly evolve to include an eval-

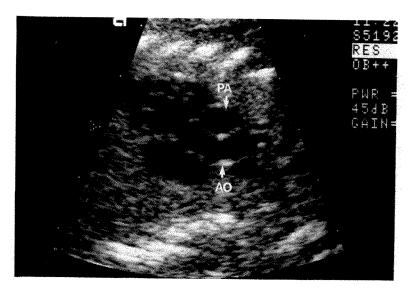

Fig. 1. Long-axis view shows aorta (AO) and pulmonary artery (PA). Measurement of aorta would be obtained at level of arrowheads (inner-to-inner). Pulmonary artery would not be measured from this view because it may not be at level of valve.

uation of the pulmonary artery and aorta in an attempt to detect these additional heart defects. In addition, a glimpse of the great vessels is sometimes possible when an adequate four-chamber view cannot be obtained because of technical factors such as fetal age, motion, or lack of fluid.

Since the size of the pulmonary artery and aorta reflects the relative flows through the right and left sides of the heart, an abnormal relative size of either vessel may imply disturbed flow associated with an underlying congenital heart defect. Although measurements of each individual vessel can be obtained, we have observed that in some fetuses the great vessels seemed disparate in size in spite of the fact that the measurement of each vessel was by itself normal or near normal. This study was an attempt (1) to establish the normal size relationship (pulmonary artery/aorta) at varying fetal ages, (2) to determine whether that relationship is age dependent, and (3) to determine whether it could contribute additional information to the evaluation of the fetal heart.

Methods

The pulmonary artery and aorta diameters were measured at the level of their respective valves from inner wall to inner wall in each of 316 fetuses from 14 to 39 weeks' gestational age from February to November 1990. Measurements were taken in real-time B-mode in either systole or diastole, because it has been previously shown that there is very little variation in size during the cardiac cycle.' A view showing the vessel longitudinally along with the valve itself was deemed acceptable (usually the short-axis view for the pulmo-

nary artery and the long-axis for the aorta, Fig. 1). No measurements were made in cross-sectional views of the vessel in question. Only those fetuses who were normally grown for dates (femur length, estimated fetal weight, abdominal and head circumference, and head circumference/abdominal circumference ratio between the 5th and 95th percentiles) and in whom both vessels could be measured were included. All fetuses with any ultrasonographic anomaly other than mild hydronephrosis or single umbilical artery were excluded from this normal group. The diameters of the aorta and pulmonary artery were plotted against estimated gestational age rather than estimated fetal weight, because it has been previously demonstrated that they are more closely related to age than fetal weight. Linear regression analysis was used to examine the relationship between estimated gestational age and pulmonary artery and aorta diameter. The 5th and 95th percentiles for the normal population were calculated from 14 to 39 weeks. A similar analysis was performed for the pulmonary artery/aorta ratio of each fetus, yielding the mean value and the upper and lower limits of normal (95th and 5th percentiles) for the normal population.

The pulmonary artery and aorta diameters of 21 fetuses with congenital heart disease were obtained retrospectively from our records. Nineteen of these 21 were identified in the antenatal period. Most were incidental findings during our routine four- and fivechamber views of the heart on all fetuses ≥15 weeks. However, several were referred because of suspected anomalies. Thirteen were diagnosed in the 10-month period during which normal measurements were made. but eight had been identified in the prior year. Only

Fig. 2. Pulmonary artery diameter versus fetal age. Pulmonary artery = 0.0313 estimated gestational age (EGA) - 0.235. There is close correlation with age (r = 0.94).

fetuses in whom there were simultaneous measurements of both great vessels and in whom there was autopsy or neonatal confirmation were included.

Results

Pulmonary and aorta diameters increase with gestational age in the normally grown fetus (r = 0.94) (Figs. 2 and 3). The mean pulmonary/aorta ratio is 1.09, with a range (± 2 SD) from 0.75 to 1.43 (Fig. 4). This ratio appears to be independent of fetal age. Beyond 20 weeks' gestational age there were no normal fetuses with a ratio <0.75.

The pulmonary artery/aorta ratio was <0.75 in the four fetuses with tetralogy of Fallot. Conversely, it was normal in four fetuses with uncomplicated ventricular septal defects (Fig. 5).

The pulmonary artery/aorta ratio was high in fetuses with tricuspid atresia with transposition, coarctation, double-outlet right ventricle, hypoplastic left heart, and an interrupted aortic arch. It was low in fetuses with tricuspid atresia and tetralogy of Fallot (Fig. 6).

There were ten sets of measurements in seven fetuses with congenital heart disease in which one vessel was normal-sized and the other normal or just beyond the normal range but in which the pulmonary artery/aorta ratio was very abnormal: coarctation, n=1; hypoplastic left heart, n=1; tricuspid atresia, n=2; and tetralogy of Fallot, n=3.

The positive predictive value was 33%, the negative predictive value 98%, sensitivity 54%, and specificity 96% on the basis of 13 cases of cardiac heart disease discovered during the period in which normal measurements were obtained. Eight cases of cardiac heart disease were detected before that period and are not included in these calculations.

Comment

Two other studies have evaluated the relationship between the size of each of the great vessels and either fetal weight or gestational age. Sahn et al.³ found a weak correlation between the size of the pulmonary artery and aorta and fetal weight (pulmonary artery, r=0.68; aorta, r=0.66). Our data relating pulmonary artery and aorta diameters to gestational age (rather than weight) closely approximate those of Cartier et al.,¹ in which size of the great vessels was found to be significantly related to age in 406 fetuses (pulmonary artery, r=0.96; aorta, r=0.94). The same group found that the aorta and pulmonary artery diameters continue to enlarge at age-approximate rates even if the fetus is growth retarded, confirming a relation to age rather than weight.²

Two smaller studies also have evaluated the actual ratio of the sizes of the pulmonary artery to aorta in individual fetuses. In a two-part study Angelini et al. found that, although the fetal pulmonary artery was

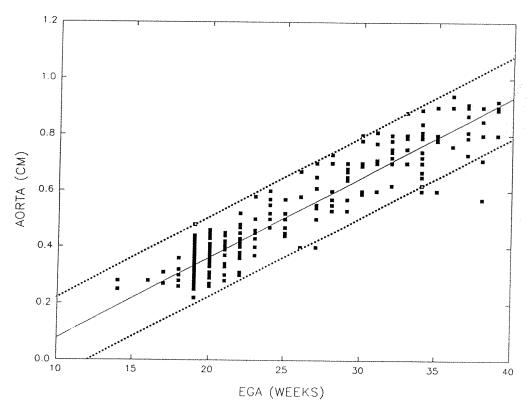

Fig. 3. Aorta diameter versus fetal age (r = 0.94).

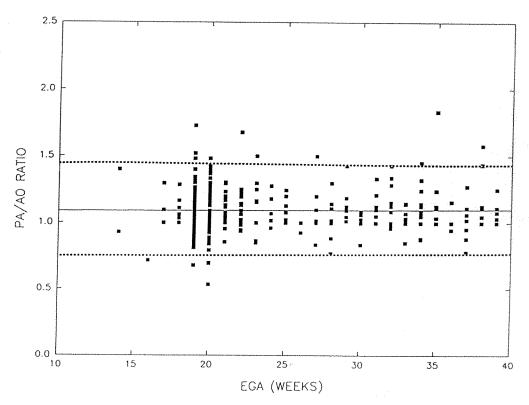

Fig. 4. Pulmonary artery/aorta (PA/AO) ratio versus age (EGA). Mean is 1.09 (SD = 0.17) and range (± 2 SD) is 0.75 to 1.43. This ratio is independent of fetal age.

Fig. 5. Pulmonary artery/aorta (PA/AO)-ratio in fetuses with tetralogy of Fallot (\blacksquare) versus ventricular septal defect (\bullet) and atrioventricular septal defect (\bullet). Mean = 1.09; 50 = 0.17. EGA, estimated gestational age. Dotted lines connect measurements in same fetus.

always larger than the aorta in 20 fetal echocardiograms, in postmortem fetuses the pulmonary trunk was larger than the aorta in 24 cases, equal in size in five, and smaller in one. More specifically, Sahn et al.³ found the pulmonary artery/aorta ratio to have a mean of 1.18 (vs 1.09 in our study) and to be independent of fetal weight in 69 fetuses with estimated weights of 500 to 3400 gm.

We found the mean pulmonary artery/aorta ratio to be slightly less (1.09) and confirm with a larger group (n=316) that it is independent of fetal age. Unlike Angelini et al., we did find that the aorta was larger than the pulmonary artery (pulmonary artery/aorta <1.0) in some normal fetuses (all values <1.0 on Fig. 4). However, in no normal fetus with a gestational age > 20 weeks was the ratio <0.75. The pulmonary artery/aorta ratio was >1.43 in only seven normal fetuses with a gestational age of >20 weeks (i.e., the pulmonary artery was rarely >50% larger than the aorta).

The pulmonary artery/aorta ratio was abnormal in 13 of 21 fetuses with congenital heart disease and normal in eight. As expected, not all fetuses with congenital heart disease have an abnormal ratio; it was normal in fetuses with ventricular septal defects, in a fetus with a ventricular septal defect and a straddling tricuspid valve, and in all fetuses with atrioventricular septal defects. It should be noted that in each of these defects

the blood flow patterns in the pulmonary artery and aorta would be normal in utero. However, the pulmonary artery/aorta ratio did effectively discriminate between four fetuses with ventricular septal defects and four with tetralogy of Fallot.

In fact, in seven cases in which one vessel was normal-sized and one measured near the outer limits of normal, the ratio accentuated the abnormal relationship in a manner similar to that in which the head/abdominal circumference accentuates the abnormal relationship of two measurements that may each be within normal range (tricuspid atresia, 2/2 cases; hypoplastic left heart, 1/1; and coarctation 1/1). This was particularly true in three cases of tetralogy of Fallot in which the aorta was only slightly large (n = 2) or normal in size (n = 1), the pulmonary artery diameter was normal, and yet the pulmonary artery/aorta ratio was abnormal. Since the ventricular septal defect in these fetuses can be difficult to see, comparison of vessel size may be the first suggestion that an abnormality exists.

Evaluation of the size relationship of the pulmonary artery to aorta is not intended to replace actual measurement or Doppler interrogation of the great vessels in the evaluation of the suspected abnormal fetal heart. However, because of position, shadowing by ribs, lack of fluid or fetal motion, Doppler data or even an adequate four-chamber view of the heart is not always

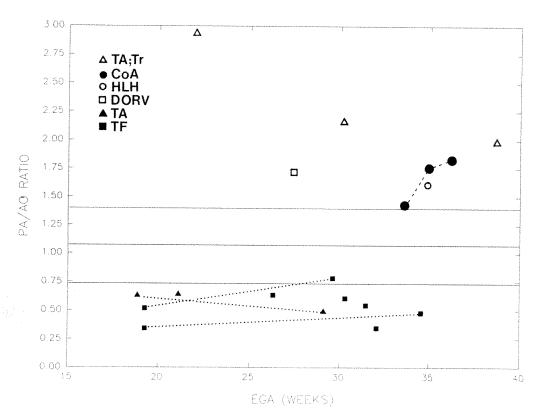

Fig. 6. High pulmonary artery/aorta (PA/AO) ratios occur in fetuses with increased pulmonary artery flow and decreased aortic flow. Mean = 1.09; SD = 0.17. △, Tricuspid atresia with transposition; ●, coarctation or interrupted arch; □, left hypoplastic heart; □, double-outlet right ventricle. Low pulmonary artery/aorta ratio is found in fetuses with decreased pulmonary artery flow and increased aortic flow. ■, Tetralogy; △, tricuspid atresia; EGA, estimated gestational age.

Fig. 7. Aorta is obviously much larger than pulmonary artery in this fetus with tetralogy of Fallot (short-axis view). In fact, pulmonary artery/aorta ratio is 0.5, which is well below 2 SD below normal. PA, Pulmonary artery; AO, aorta.

obtainable. In addition, Doppler measurements of velocity are often time-consuming and therefore not a practical part of a screening examination. Actual measurement of the vessels also can be difficult and may

be misleading if one measurement is high-normal and the other low-normal. A quick comparison of relative size by simple inspection is feasible during the course of a screening examination, because the pulmonary artery and aorta cross each other near their origins. If the pulmonary artery appears to be >50% larger or >25% smaller than the aorta (Fig. 7), a closer examination of the heart is suggested. This ratio has the added advantage of being useful even when fetal age is unknown, because it appears to be independent of age and weight.

Transverse cerebellar diameter: A useful predictor of gestational age for fetuses with asymmetric growth retardation

Wesley Lee, MD, Scott Barton, MD, Christine H. Comstock, MD, Stephanie Bajorek, RDMS, Daniel Batton, MD, and Janet S. Kirk, MD

Royal Oak, Michigan

There have been conflicting reports regarding the ability of cerebellar diameter to satisfactorily predict the gestational age of growth-retarded fetuses. Gestational age prediction intervals were derived from 270 normal fetuses between 14 and 40 weeks' gestation for biparietal diameter, head circumference, abdominal circumference, femur length, and transverse cerebellar diameter. We evaluated the ability of these parameters to predict gestational age for 19 small-for-gestational-age fetuses. The cerebellar diameter regression model led to the smallest differences between observed and predicted gestational age for all growth-retarded fetuses. Transverse cerebellar diameter satisfactorily predicted gestational age for all six fetuses with asymmetric intrauterine growth retardation and was associated with the least amount of underestimation bias when compared with other ultrasonographic parameters. However, transverse cerebellar diameter appeared to be no better than biparietal diameter, head circumference, or femur length for accurately predicting gestational age of fetuses with symmetric intrauterine growth retardation (n = 13) despite the finding that cerebellar growth was also relatively spared under these circumstances. We conclude that transverse cerebellar diameter can be used to reliably approximate gestational age in fetuses with asymmetric intrauterine growth retardation. However, caution is warranted when using it to predict the gestational age of fetuses affected by symmetric intrauterine growth retardation. (Am J Obstet GYNECOL 1991;165:1044-50.)

first time during the second or third trimester with confusing gestational dating criteria. Early ultrasonographic information is not always available to verify gestational age on the basis of menstrual history alone. A significant correlation between transverse cerebellar diameter and gestational age has been previously reported, but the actual relationship between these two variables remains controversial for growth-retarded fetuses. We have observed some small-for-gestationalage (SGA) fetuses to have transverse cerebellar diameter measurements that were minimally affected by IUGR. Therefore the potential application of such

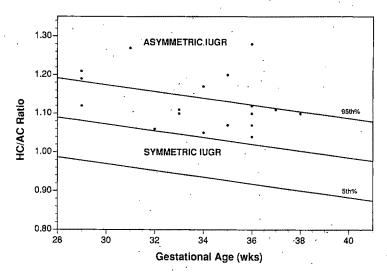

Fig. 1. Head circumference/abdominal circumference (HC/AC) ratio prediction intervals (95th percentile) for 270 normal fetuses.

measurements to reliably estimate gestational age from SGA fetuses was systematically investigated.

Material and methods

Normal population. Obstetric ultrasound scans at William Beaumont Hospital were retrospectively examined over a 2-year period. Ultrasound data were obtained from 270 normal fetuses between 14 and 40 weeks' gestation by Acuson 128 (Mountain View, Calif.), General Electric RT 3000 (Milwaukee), and Aloka 650 (Corometrics, Wallingford, Conn.) imaging systems. Standard measurements included biparietal diameter, head circumference, abdominal circumference, femur length, and transverse cerebellar diameter. Transverse cerebellar diameter measurements were obtained from the outer to outer margins of the cerebellum in the posterior fossa. All fetuses had excellent ultrasonographic dating criteria before 20 weeks' gestation and were found to be subsequently normal by neonatal examination. Gestational ages were rounded off to the nearest whole week. Fetuses with structural abnormalities were excluded, and all infants were delivered at our institution. This information was used to construct gestational age prediction intervals for our normal patient population.

SGA fetuses. Nineteen SGA newborns with birth weights ≤10th percentile of Brenner et al.⁵ were entered into the study from Aug. 3, 1987, to Dec. 11, 1990. Approximately 24,000 ultrasonographic examinations were conducted during this time period. All infants had normal early ultrasonographic scans before 20 weeks' gestation or an initial ultrasonographic examination before 24 weeks that was consistent with last menstrual period. These subjects also required at least one transverse cerebellar diameter measurement after 26 weeks' gestation that could be correlated with other

ultrasonographic findings. Infants with structural or genetic abnormalities were excluded from the study.

SGA fetuses were subdivided according to whether the observed head circumference/abdominal circumference ratio was within our normal population, as defined by 95th percentile prediction limits. The head circumference/abdominal circumference prediction limits were used to classify IUGR types as symmetric (values within normal prediction limits) or asymmetric (values outside of prediction limits). The last ultrasonographic examination before delivery was plotted against these normal curves to qualitatively demonstrate the ability of the regression model to predict gestational age for small fetuses. The mean difference between observed and predicted gestational age values were averaged for each ultrasonographic variable to allow quantitative comparisons between groups. All fetuses, with the exception of one case, delivered at our

Statistical and graphic analysis. Regression analysis and 95th percentile prediction intervals were calculated by JMP Macintosh software for our normal population (SAS Institute, Cary, N.C.).6 Prediction limits were designed to predict gestational age for a given ultrasonographic measurement (e.g., cerebellar diameter). This approach considers the individual variability for a given measurement. By contrast, confidence intervals compare mean values (population vs sample) and do not reflect the variability associated with a single observation. Accordingly, a value that falls within the 5th and 95th percentile prediction limits will not be significantly different from the normal population. Mean values are reported with their standard deviations. Differences between group mean values were analyzed with the Student t test.

Table I. Description of 19 fetuses with IUGR

Case No.	Delivery gestational age (wk)	Birth weight (gm)	Brenner 10th percentile (gm)	Weight difference (%)	Head circumference/abdominat circumference

Results

Table I summarizes general characteristics of 19 SGA fetuses and compares them with data of Brenner et al.⁵ Six fetuses were classified as having asymmetric IUGR on the basis of the head circumference/abdominal circumference ratio as compared with the other 13 SGA fetuses with symmetric IUGR (Fig. 1).

Fetuses with asymmetric IUGR were delivered about 5 weeks earlier than the group with symmetric IUGR (p < 0.001). Therefore fetuses with symmetric IUGR had greater birth weights than those with asymmetric IUGR (p < 0.001). All birth weights were at or below Brenner's 10th percentile. The discrepancy between actual birth weight and Brenner's 10th percentile was expressed as a percentage of the latter to estimate IUGR severity. However, the severity of IUGR did not reliably identify those fetuses that were subsequently classified with asymmetric versus symmetric growth retardation.

Gestational age was significantly correlated (second-order polynomials) with biparietal diameter, head circumference, abdominal circumference, femur length, and transverse cerebellar diameter for normally grown fetuses. Figs. 2 and 3 graphically illustrate these normal regression curves with the last ultrasonographic examination plotted for each SGA fetus before delivery. The last ultrasonographic scans for fetuses with symmetric IUGR were performed slightly later in pregnancy $(35.9 \pm 1.8 \text{ weeks})$ as compared with those of asymmetric IUGR $(33.0 \pm 3.2 \text{ weeks})$ (p < 0.02). How-

ever, all fetuses exhibited ultrasonographic evidence of IUGR before delivery. The transverse cerebellar diameter regression model qualitatively appeared to most accurately predict gestational age (50th percentile) when compared with other ultrasonographic parameters for all growth-retarded fetuses.

Table II examines SGA fetuses whose true gestational age was markedly underestimated by a particular ultrasonographic parameter on the basis of IUGR type. For all SGA cases, prediction intervals markedly underestimated gestational age on the basis of abdominal circumference (18 fetuses) or femur length (9 fetuses) alone. However, relatively fewer SGA fetuses had markedly underestimated gestational age by biparietal diameter (five fetuses), head circumference (five fetuses), and transverse cerebellar diameter (five fetuses) criteria. Biparietal diameter, head circumference, femur length, and transverse cerebellar diameter were associated with similar numbers of symmetrically growth-retarded fetuses (four to five cases in each category) with underestimated gestational age. The worse predictor, abdominal circumference, was associated with 12 symmetrically growth-retarded fetuses with markedly underestimated gestational age. An analogous but smaller pattern was also observed in six fetuses with asymmetric IUGR. Under these circumstances, six abdominal circumference and four femur length measurements were observed outside of the prediction limits. Only one asymmetrically growth-retarded fetus had underestimated gestational age on the basis of BPD or

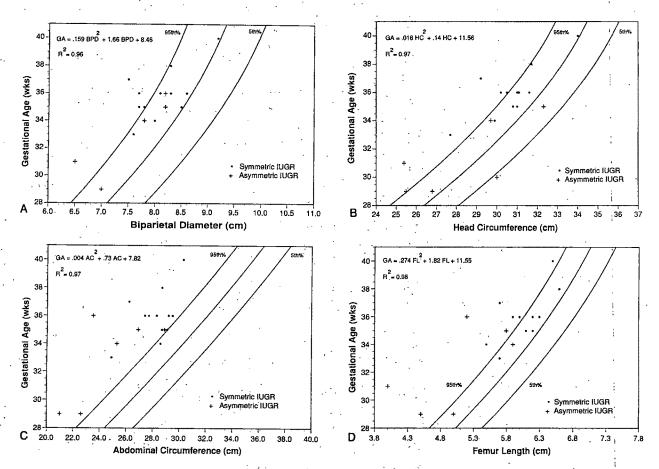

Fig. 2. Gestational age prediction intervals (95th percentile) for biparietal diameter (A), head circumference (B), abdominal circumference (C), and femur length (D) from 270 normal fetuses. Last ultrasonographic examination from 19 SGA fetuses was plotted against these curves. SGA data points are occasionally superimposed on each other. GA, Gestational age; BPD, biparietal diameter; HC, head circumference; AC; abdominal circumference; FL, femur length.

Table II. Number of SGA fetuses with underestimated gestational ages by regression models

Biparietal diameter	1 .	4	5
Head circumference	, , <u>, , , , , , , , , , , , , , , , , </u>	4	. 5
Abdominal circumference	6	12	. 18
Femur length	4	5	9
Cerebellum diameter	0 .	5	5

Note: One fetus with asymmetric IUGR (head circumference) and one fetus with symmetric IUGR (cerebellum diameter) had measurements that overestimated gestational age.

head circumference criteria. All fetuses with asymmetric IUGR had transverse cerebellar diameter measurements that fell within the gestational age prediction limits for our normal population.

Table III outlines mean differences between observed and predicted gestational age values for multiple ultrasonographic parameters. When compared with other ultrasonographic parameters, transverse cerebellar diameter was the best overall estimator for predicting true gestational age, with a mean deviation of

about 1.3 ± 1.8 weeks from the mean regression line. Symmetric IUGR cases were associated with the smallest mean deviation from predicted gestational age, despite the fact that 38% of these fetuses actually had transverse cerebellar diameter measurements outside normal limits. Similarly, transverse cerebellar diameter and head circumference were associated with the smallest deviations from predicted gestational age for asymmetric IUGR. A statistically significant difference could not be demonstrated for the degree of gestational age

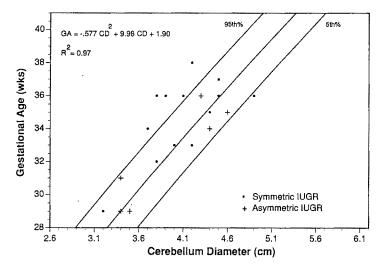

Fig. 3. Gestational age prediction intervals (95th percentile) for cerebellar diameter from 270 normal fetuses. Last ultrasonographic examination from 19 SGA fetuses was plotted against these curves. *GA*, gestational age; *CD*, transverse cerebellar diameter.

Table III. Deviation from gestational age prediction models

Measurement	Asymmetric IUGR	Symmetric IUGR	All SGA fetuses
Abdominal circumference	4.7 ± 2.3*	3.9 ± 2.0*	4.1 ± 2.1*
Femur length	$4.4 \pm 2.7*$	$3.1 \pm 1.4*$	$3.5 \pm 1.9*$
Biparietal diameter	$2.6 \pm 1.5*$	$3.9 \pm 1.6*$	$3.5 \pm 1.6*$
Head circumference	1.3 ± 2.1	$3.0 \pm 1.2*$	$2.5 \pm 1.7*$

deviation (transverse cerebellar diameter) observed between symmetric (1.7 \pm 1.9 weeks) versus asymmetric (0.3 \pm 1.2 weeks) IUGR (p < 0.10, NS).

Comment

The utility of transverse cerebellar diameter measurements for accurately estimating gestational age was examined in two ways. First, the quantitative deviation from predicted values (observed – expected gestational age) provided an index of how accurately the regression models predicted mean gestational age. Second, the actual number of growth-retarded fetuses whose true gestational ages would have been substantially underestimated by our regression models was summarized on the basis of prediction intervals established for our normal population.

Our findings confirm that ultrasonographic parameters such as biparietal diameter, head circumference, abdominal circumference, and femur length are likely to underestimate gestational age for growth-retarded fetuses. Head circumference measurements appear to have some advantages over biparietal diameter, femur length, and abdominal circumference on the basis of

mean differences found between observed and predicted values for asymmetric IUGR fetuses. However, two fetuses with asymmetric IUGR had head circumference measurements that actually fell outside the normal gestational age prediction limits. True gestational age appears to be more reliably predicted by transverse cerebellar diameter measurements for fetuses with asymmetric IUGR. For example, none of the fetuses with asymmetric IUGR had transverse cerebellar diameter measurements that fell outside the normal gestational age prediction curves. Furthermore, the cerebellum regression model led to the smallest differences between observed and predicted gestational age values for fetuses with asymmetric IUGR. Fetuses with symmetric growth retardation also demonstrated relative preservation of cerebellar growth but to a lesser degree than observed with asymmetric IUGR. Therefore the utility of transverse cerebellar diameter for predicting gestational age may be less applicable to a growth-retarded fetus whose head size has not been spared. This does not disprove the potential utility of transverse cerebellar diameter measurements for predicting the gestational age of fetuses with symmetric

IUGR but does suggest that caution is warranted under these circumstances.

These observations do not completely agree with previous studies that have examined the relationship of cerebellar diameter to SGA fetuses. Reece et al.3 compared 19 growth-retarded fetuses with their normal population. They were not subdivided according to IUGR type (asymmetric vs symmetric). Neonatal birth weights were ≤10th percentile according to the criteria of Usher and McLean7 or Battaglia and Lubchenco.8 All cerebellar measurements fell within normal gestational age ranges, which led to their conclusion that transverse cerebellar diameter was unaffected by growth retardation. Their findings were also similar to those recently reported by French investigators9 who also found transverse cerebellar diameter growth not to be greatly affected by 12 cases of severe IUGR. By contrast, Hill et al.4 subsequently reported severe limitations for predicting gestational age by cerebellar diameters from 44 SGA fetuses. Dating criteria was established by regular cyclic menses with an early pelvic examination before 10 weeks' gestation. The diagnosis of IUGR was confirmed by comparing birth weight with the criteria of Babson et al.10 More than half of their SGA fetuses (59%) had transverse cerebellar diameter measurements that fell >2 SD below the mean.

It is possible that studies in which transverse cerebellar diameter was found to be unaffected by growth retardation may be influenced heavily by a greater proportion of fetuses with asymmetric IUGR, because these investigators did not subclassify their subjects by head-to-body disproportion.3,9 It is presently unclear as to why our conclusions do not agree with the work reported by Hill et al., since they also subdivided their SGA fetuses on the basis of IUGR type.4 Unlike our study, they found no differences in the proportion of transverse cerebellar diameter measurements falling outside the normal range (2 SD) between symmetric (eight of 14 fetuses, 57%) versus asymmetric IUGR (18 of 30 fetuses, 60%). One major difference might have resulted from the definition of asymmetric and symmetric IUGR on the basis of head circumference/abdominal circumference ratio. Hill et al. used the original criteria of Campbell and Thoms11 to identify symmetric and asymmetric IUGR. The regression model used in our study was very similar to Campbell and Thoms' nomogram. Therefore it seems unlikely that these differences can be attributed to misclassification of symmetric versus asymmetric IUGR on the basis of head circumference/abdominal circumference ratio.

The actual influence of IUGR on the newborn primate cerebellum remains controversial. For example, Chase et al.12 studied brain weights in seven averagefor-gestational-age and four SGA infants at term gestation who died in the newborn period from a variety of causes, such as congenital heart disease, sepsis, lung disease, and subarachnoid hemorrhage. They found cerebellar weights from SGA fetuses to be reduced by 37% of appropriate-for-gestational age fetuses. Co et al.13 recently compared neonatal cerebellar dimensions by ultrasonography that involved 81 preterm infants (25 to 42 weeks) and 19 SGA infants that were matched for gestational age. Cerebellar dimensions were similar, and it was concluded that cerebellar growth was not significantly influenced by growth retardation. Unfortunately, their newborns were not classified on the basis of head-to-body disproportion. In this regard, in utero microsphere studies of term nonhuman primate fetuses (Mucaca mulatta) have also demonstrated preservation of cerebellar blood flow in spite of experimental asphyxia induced by maternal hypoxia.14 Our results support the hypothesis that human cerebellar growth is relatively resistant to IUGR when compared with other fetal structures that are commonly measured by prenatal ultrasonography.

In summary, the heterogeneous nature of IUGR will pose considerable challenges for making the diagnosis early enough to implement appropriate obstetric management. Transverse cerebellar diameter measurements appear to reasonably estimate gestational age for asymmetrically growth-retarded fetuses, where an abnormal head circumference/abdominal circumference ratio probably reflects a brain-sparing phenomenon related to uteroplacental insufficiency. Use of other common ultrasonographic measurements such as abdominal circumference and femur length may markedly underestimate gestational age under these circumstances but will provide useful information for a basis of comparison, especially when combined with the amniotic fluid status. By contrast, the ability of transverse cerebellar diameter measurements for predicting gestational age may be less applicable to fetuses with symmetric IUGR. This information should be especially useful for fetuses with suspected IUGR and poor early dating criteria when it is very difficult to distinguish between true growth retardation versus incorrect dates.

We thank Mr. Daniel Barth-Jones for his statistical assistance.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Comparison of humerus length with femur length in fetuses with Down syndrome

John F. Rodis, MD, Anthony M. Vintzileos, MD, Alfred D. Fleming, MD, Leslie Ciarleglio, MS, Deborah A. Nardi, RRT, RDMS, Lori Feeney, RRT, RDMS, William E. Scorza, MD, Winston A. Campbell, MD, and Charles Ingardia, MD

Farmington and Hartford, Connecticut

A recent report by FitzSimmons et al. demonstrated a greater frequency of upper- versus lower-extremity shortening in autopsies of second-trimester fetuses with trisomy 21. We undertook this study to determine whether this upper-limb shortening could be detected by prenatal ultrasonography in the second trimester and therefore identify fetuses at risk for trisomy 21. A restospective review of all prenatal sonograms preceding genetic amniocentesis was conducted. Between 1987 and 1990 11 consecutive fetuses between 15 and 22 weeks' gestation with trisomy 21 were identified by genetic amniocentesis. Femur and humerus lengths were plotted on growth curves created from 1470 normal patients between 12 and 26 weeks. Gestational age was confirmed by last menstrual period and biparietal diameter. In fetuses with trisomy 21, seven of 11 humeri were <5th percentile, for a sensitivity of 64%, whereas only two of 11 femurs were <5th percentile, for a sensitivity of 18%. Biparietal diameter/femur length and biparietal diameter/humerus length ratios were also tested to predict Down syndrome. In only 2 of 11 cases was the biparietal diameter/femur length ratio >95th percentile, whereas the biparietal diameter/humerus length ratio was >95th percentile in 7 of 11. Since all seven were identified by shortened humerus alone, we conclude that humerus length versus gestational age is the simplest and most effective screen. The positive predictive value of an abnormally short humerus length in detecting Down syndrome was 6.8% in our population where the prevalence of Down syndrome was 1 of 173. The present study supports the observations of FitzSimmons et al. that shortened humerus length has a greater sensitivity than femur length in cases of trisomy 21. We conclude that in fetuses at risk for trisomy 21 humerus length should be determined, because it may, if shortened, aid in the prenatal diagnosis. (AM J OBSTET GYNECOL 1991;165:1051-6.)

Key words: Down syndrome, prenatal diagnosis, humerus length

The prenatal diagnosis of Down syndrome has relied primarily on genetic amniocentesis or, more recently, on chorionic villus sampling, in women ≥35 years of age. Even if all women 35 or older underwent prenatal diagnostic testing, approximately 80% of Down syndrome would not be detected, because it occurs in the 95% of childbearing women that are under 35. Moreover, many women (even those at high risk) choose not to have invasive genetic testing for fear of miscarriage following the procedure. Therefore a noninvasive test to either detect or rule out Down syndrome would be

6/6/30948

beneficial. Ultrasonographically detected abnormalities associated with Down syndrome include increased nuchal skin thickening,1 short femur length, abnormal biparietal diameter/femur length ratio,2 duodenal atresia,3 omphalocele,4 cardiac defects,5 cystic hygromas,6 and nonimmune hydrops. However, these findings are not consistently found in most fetuses with Down syndrome. FitzSimmons et al.,8 using radiographs of embryo specimens, recently described long-bone growth in cases of Down syndrome and reported that shortening of the upper extremity was more pronounced than that of the lower extremity. We undertook this study to determine if the obstructions of shortened humeri of FitzSimmons et al.8 could be extended to ultrasonographic observations and thus to determine if fetal humerus length measurements in the second trimester could be helpful in detecting Down syndrome prenatally. Therefore the purpose of this study was to make second-trimester nomograms for humerus length and biparietal diameter/humerus length ratio versus gestational age and humerus length versus biparietal

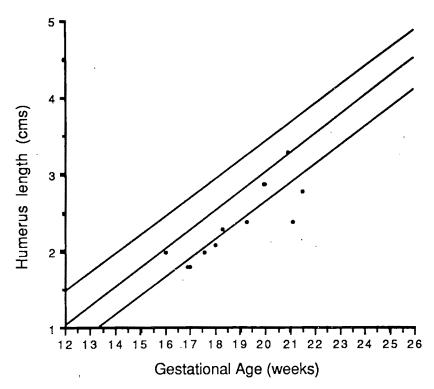

Fig. 1. Relationship between humerus length and gestational age in second trimester. Shown are 5th, 50th, and 95th percentiles. Closed circles, Fetuses with Down syndrome.

diameter in our population, to retrospectively identify fetuses with Down syndrome detected by genetic amniocentesis, to determine the sensitivity of humerus length and femur length to identify Down syndrome at different cutoff values (e.g., 5th and 10th percentiles), and to determine efficacy of an abnormal humerus length to predict Down syndrome in our population of genetic amniocentesis over a $2\frac{1}{2}$ -year period.

Material and methods

Nomograms were established from 1470 ultrasonographic examinations performed between 12 and 26 weeks' gestation in patients with a certain last menstrual period. In all cases the estimated gestational age, as established by last menstrual period, was within 1.5 weeks of the gestational age estimated by ultrasonography. Measurements obtained at each examination included biparietal diameter, head circumference, femur length, humerus length, and abdominal circumference. Fetuses with known congenital or chromosomal anomalies were excluded. This portion of the study was crosssectional; patients were included once. All examinations were performed between Jan. 1, 1988, and June 30, 1990, by members of the Division of Maternal-Fetal Medicine at the University of Connecticut Health Center and Hartford Hospital with General Electric RT 3000 (Milwaukee) and Acuson 128 (Mountain View, Calif.) real-time ultrasonography machines with freezeframe capabilities and on-screen calipers. Linear and polynomial regression analyses were performed to describe the relationships between humerus length versus gestational age, humerus length versus biparietal diameter, biparietal diameter/humerus length ratio versus gestational age, and biparietal diameter/femur length ratio versus gestational age. The 5th, 10th, 50th, 90th, and 95th percentiles were calculated. All patients who come through our antepartum testing unit are given outcome cards to complete; about 75% return these.

Records of all patients undergoing second-trimester genetic amniocenteses over the 2½-year study period were reviewed to identify all cases of Down syndrome diagnosed prenatally and to determine the prevalence of Down syndrome in this population. Over this study period, 1907 genetic amniocenteses were performed. Indications included advanced maternal age (77%), low maternal serum α-fetoprotein value (20%), and previous child with trisomy (3%). At the time of amniocentesis, ultrasonographic measurements including biparietal diameter, head circumference, femur length, humerus length, and abdominal circumference were obtained.

Results

During the study period 11 fetuses with Down syndrome were identified by second trimester genetic am-

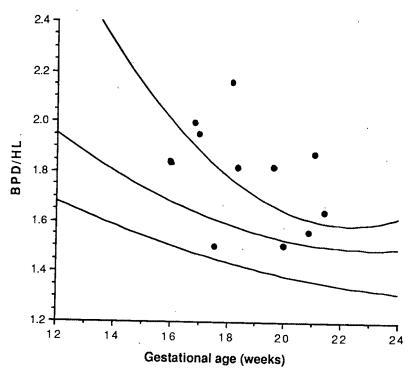

Fig. 2. Relationship between biparietal diameter/humerus length (BPD/HL) ratio versus gestational age. Shown are 5th, 50th, and 95th percentiles. Closed circles, Fetuses with Down syndrome.

niocentesis. We compared the humerus length in these 11 cases with the curves established in the 1470 normal patients (Fig. 1) and found that in seven of 11 cases (sensitivity, 64%) the humerus length fell below the 5th percentile from the norm for that gestational age. If the 10th percentile was chosen as a cutoff, the sensitivity remained at 64%. In all 11 cases, the humerus length fell below the 50th percentile. The relationship between humerus length and gestational age is described by the linear equation humerus length = 0.241 gestational age -1.787 (r = 0.939, $R^2 = 0.88$, p = 0.0001). The biparietal diameter/humerus length ratio versus gestational age is illustrated in Fig. 2; the relationship is described by the second-order polynomial equation biparietal diameter/humerus length = 3.834 - 0.204 gestational age + 0.004 gestational age² (r = 0.517, $R^2 = 0.26, p = 0.0001$). Seven of 11 fetuses with Down syndrome had biparietal diameter/humerus length ratios >95th percentile, with the same seven being <90th percentile with no new cases identified. The relationship between humerus length and biparietal diameter is shown in Fig. 3 and is described by the linear equation humerus length = 1.146 biparietal diameter + 1.14 $(r = 0.936, R^2 = 0.877, p = 0.0001)$. Five of 11 cases (45%) of Down syndrome had humerus length <5th percentile, with the sensitivity improving to seven of 11 (64%) if the 10th percentile was used as the cutoff. During the study period, six cases of trisomy 18 and no cases of trisomy 13 were identified. Only two of the six cases (sensitivity, 33%) of trisomy 18 had humerus length <5th percentile.

Abnormal femur length measurements were not as sensitive in detecting Down syndrome in comparison with humerus length. When femur length versus gestational age was considered, only two of 11 cases were below the 5th percentile and three of 11 below the 10th percentile. The biparietal diameter/femur length ratio versus gestational age (Fig. 4) identified two of 11 cases and three of 11 cases at the 95th and 90th percentile, respectively. The relationship between biparietal diameter/femur length and gestational age is described by the second-order polynomial equation biparietal diameter/femur length = 3.82 - 0.197 gestational age + 0.004 gestational age² (r = 0.59, $R^2 = 0.348$, p = 0.0001). Femur length versus gestational age identified only one of 11 and three of 11 cases at the 95th and 90th percentiles, respectively.

We concluded from these analyses that the humerus length versus gestational age was the simplest and most efficacious and thus the most practical ultrasonographic screening test for Down syndrome. The 5th percentile humerus length for gestational ages from 12 to 26 weeks is shown in Table I. Over the 21/2-year study period, 1907 genetic amniocenteses were performed at the University of Connecticut Health Center (1431 cases) and Hartford Hospital (476 cases). Eleven cases of Down syndrome were identified in the 1907 cases, for an overall prevalence of 1 in 173. The sensitivity,

specificity, and positive and negative predictive value of humerus length versus gestational age is shown in Table II. An abnormally short femur length was not as sensitive as humerus length in detecting Down syndrome, as indicated in Table III. The positive predictive value of an abnormally short (<5th percentile) humerus length was 6.8% in our population of patients seen for genetic amniocentesis, who had a prevalence of Down syndrome of 1 in 173. Moreover, a normal humerus length measurement (≥5th percentile) would rule out Down syndrome in 99.7% of cases (negative predictive value).

Comment

Since 1970, very little has changed in regard to prenatal diagnosis of Down syndrome. The emphasis has been on testing women of advanced maternal age, although only 20% of Down syndrome occurs in that age group. Recently, maternal serum α -fetoprotein testing has been incorporated into the prenatal diagnostic testing schema, because women who are carrying fetuses with Down syndrome have been shown to have lower levels of maternal serum α -fetoprotein. If all women under 35 had routine maternal serum α-fetoprotein screening, another 20% of Down syndrome cases would be identified.9 More recently, fetal ultrasonography has been suggested as an additional tool to aid in prenatal detection of Down syndrome. However, this method has not been very practical for the average clinician for several reasons. First, while some anomalies are frequently associated with Down syndrome they are not present in the majority of cases. For example, while 30% to 40% of fetuses with duodenal atresia prove to have Down syndrome, only 5% of fetuses with Down syndrome have duodenal atresia. 10 Second, some of the anomalies associated with Down syndrome are not readily detectable until the third trimester, when elective pregnancy termination is no longer an option for the parents. Duodenal atresia is one example, where the classic "double bubble" finding in association with polyhydramnios is not usually visualized before 24 weeks.3 Third, some of the ultrasonographic findings may not be readily apparent or easy to obtain for the average sonographer on a routine examination.

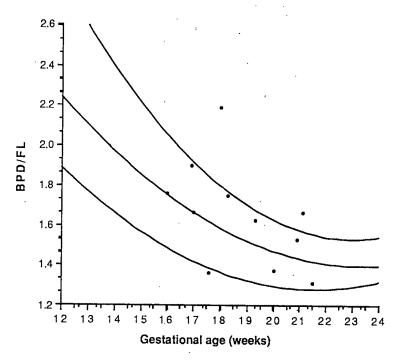

Fig. 4. Relationship between biparietal diameter/femur length (BPD/FL) ratio versus gestational age. Shown are 5th, 50th, and 90th percentiles. Closed circles, Fetuses with Down syndrome.

Examples include nuchal skin thickening, cardiac defects, and hypoplasia of the middle phalanx of the fifth finger.11 Fourth, some mathematic calculations may be required, as in the case of biparietal diameter/femur length ratio. Moreover, the sensitivity of this ratio to detect Down syndrome has recently been questioned.12

Humerus length measurements, on the other hand, are easy to obtain. Long-bone measurements, particularly the femur length, are included in most, if not all, second-trimester ultrasonographic examinations. Including the humerus length as part of the routine examination requires no special expertise in obstetric ultrasonography and would add very little time to the examination. No ratios need to be calculated. In our population 64% of cases of Down syndrome would have been identified by this simple prenatal screening method, whereas <5% of normal fetuses had an abnormally short humerus length.

Our findings appear to agree with the recent observations of Benacerraf et al.18 They found that if the actual-to-expected humerus length ratio was ≤0.90, they were able to detect 12 of 24 fetuses with Down syndrome (sensitivity, 50%) with a 6.25% false-positive

It would appear that if our findings are confirmed, fetal humerus length measurements should be obtained at any second-trimester ultrasonographic examination. If the humerus length falls below the 5th percentile, prenatal genetic testing should be offered to the pa-

Table II. Efficacy of humerus length to predict Down syndrome

	Down syndrome	Normal	Total
Humerus length <5th percentile	7	95	102
Humerus length ≥5th percentile	4	1795	1799
TOTAL	11	1890	1901*

Sensitivity, 7 of 11 (64%); specificity, 1795 of 1890 (95%); positive predictive value, 7 of 102 (7%); negative predictive value, 1795 of 1799 (99.7%).

Table III. Efficacy of femur length to predict Down syndrome

	Down syndrome	Normal	Total
Femur length <5th percentile	2	95	97
Femur length ≥5th percentile	9	1795	1804
TOTAL	11	1890	1901*

Sensitivity; 2 of 11 (18%); specificity; 1795 of 1890 (95%); positive predictive value; 2 of 97 (2%); negative predictive value; 1795 of 1804 (99.5%).

^{*}The six cases of trisomy 18 were excluded.

^{*}The six cases of trisomy 18 were excluded.

tient. This may prove to be an effective way of identifying fetuses with Down syndrome in a low-risk population, specifically women <35 years old. We are prospectively evaluating the efficacy of an abnormal humerus length to predict Down syndrome in such low-risk women.

Ultrasonographic diagnosis of congenital anomalies in twins

Steven R. Allen, MD, Leslie J. Gray, MD, Barbara H. Frentzen, MSN, and Amelia C. Cruz, MD

Gainesville, Florida

To determine whether serial ultrasonographic examinations with basic anatomic surveys provide an adequate screen for congenital abnormalities that are more common in twins, we compared the results of prenatal sonograms and neonatal examinations for 314 twins (157 pairs) delivered during a recent 42-month period. An anomaly was defined as major if it potentially required surgical repair or precluded normal life expectancy; otherwise it was defined as minor. Thirty-three twins (9.5%) had 40 anomalies; 28 (9%) were major and 12 (4%) were minor. Prenatal ultrasonography with cardiac screening limited to the four-chamber view provided detection of 39% of all major anomalies, 55% of noncardiac major anomalies but none of the cardiac lesions, and 69% of the major anomalies for which routine prenatal management should be altered. No false-positive diagnoses incorrectly altered management. We conclude that serial prenatal ultrasonographic examinations are useful in detecting noncardiac anomalies for which twins are at increased risk, but the four-chamber view is not an adequate screen for the cardiac malformations of twins. (Am J Obstet Gynecol 1991;165:1056-60.)

Twins are known to have an increased risk of congenital anomalies, up to threefold higher than for singletons¹⁻⁵; however, the value of ultrasonography in the diagnosis and management of the anomalies of twins has not been proved. To determine whether ultrasonographic examinations that include a basic ana-

tomic survey provide an adequate screen for clinically significant congenital defects in twins, we compared the results of prenatal sonograms and neonatal examinations for twins delivered during a recent 42-month period.

Material and methods

Subjects. Mothers whose ultrasonographic examinations were included in the study received their prenatal care from the Department of Obstetrics and Gynecology of the University of Florida and were delivered at Shands Hospital. The twins were born between Sept. 1, 1986, and Jan. 31, 1990. Details of the sonograms were obtained from each mother's prenatal record. Additional perinatal data were obtained from a computerized data base and the registry of the labor and delivery unit.

The University of Florida Department of Obstetrics and Gynecology provides prenatal care and ultrasonographic services for high-risk patients referred from the county health clinics of north-central Florida. Fiftyone percent of the generally low-income patients are white, 47% are black, and 2% are Hispanic or Asian.

Methods. Each twin pair had at least one prenatal sonogram available for review. Ultrasonographic examinations were scheduled every 3 to 4 weeks and were performed according to the recommendations of the American College of Obstetricians and Gynecologists, including evaluation of fetal number and presentation, amniotic fluid volume, gestational dating, placental localization, and an anatomic survey of the head, heart (four-chamber view), spine, stomach, kidneys, bladder, abdominal wall, and extremities.6,7 Each examination was performed by a registered diagnostic medical sonographer or a perinatologist. A congenital anomaly was defined as major if it potentially required surgical repair or precluded normal life expectancy; otherwise it was defined as minor.8

To determine the accuracy of ultrasonography in determining congenital abnormalities, ultrasonographic findings were compared with those of physical examinations performed by staff neonatologists. Fetal gender and membrane chorionicity and amnionicity were reviewed to potentially determine the zygosity of twin pairs in pregnancies complicated by congenital malformations, but other tests to confirm zygosity were not performed. Because abnormalities were relatively infrequent, only descriptive statistics are presented.

Results

During the study period, 342 twins (171 pairs) were delivered, for an incidence of twin gestations of 1.6%. Of these, 314 (157 twin pairs) had at least one prenatal ultrasonographic examination and were included in the study population. The mean number of sonograms per

patient was 2.5. Thirty-three infants (9.5%) had 40 anomalies detected during neonatal examination, including two twins with multiple major malformations. Of these 40 malformations, 28 (9%) were major and 12 (4%) were minor.

The most common major anomalies involved the genitourinary system, with an incidence of 14 in 314 (5%), as indicated in Table I. Six (43%) of these were detected by prenatal ultrasonographic examination. With serial examinations, one case of hydronephrosis was detected on a third-trimester scan after a normal scan during the second trimester. The next most common major abnormalities were cardiovascular, with eight structural defects documented in five infants. None of these lesions were diagnosed prenatally by ultrasonography. However, prenatal ultrasonographic examinations did detect all cases of nonimmune hydrops, osteogenesis imperfecta (IB), and omphalocele. None of the minor anomalies was detected prenatally. No false-positive prenatal diagnoses were made.

Serial basic ultrasonographic examinations provided 39% sensitivity, 100% specificity, 100% positive predictive value, and 91% negative predictive value for the detection of all major congenital anomalies; however, prenatal diagnosis by ultrasonography would not be expected for several of these anomalies. Table II shows the sensitivity of prenatal ultrasonography in this population for the diagnosis of those anomalies reportedly predictable by ultrasonography.

Major anomalies in this twin population that might alter routine prenatal management are hydronephrosis, bladder outlet obstruction, bilateral renal dysplasia, cloacal exstrophy, tricuspid atresia, pulmonary stenosis, right ventricular hypoplasia, nonimmune hydrops, osteogenesis imperfecta (IB), and omphalocele. Of 16 such malformations, 11 were correctly diagnosed by routine prenatal ultrasonography, yielding a sensitivity of 69%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 95%.

Among the 33 twins with congenital malformations, 5 (15%) were monochorionic and thus certainly monozygotic; 16 (49%) were dichorionic, of the opposite sex and therefore dizygotic; and 12 (36%) were dichorionic, of the same sex and therefore of unsure zygosity. Five twin pairs had concordant malformations. One dizygotic pair had osteogenesis imperfecta (IB) and one monozygotic pair had hydroceles. Two pairs of unsure zygosity (dichorionic, same sex) were concordant for hypospadias and hydroceles, respectively. Another twin pair of unsure zygosity, concordant for tricuspid atresia, had other dissimilar major anomalies.

Gynecologists, serial prenatal ultrasonographic examinations, which included a basic anatomic survey, were predictive of the majority of noncardiac major congenital malformations in twins. Considering only those malformations for which a prenatal diagnosis would lead to an alteration in routine perinatal management, serial basic ultrasonographic evaluations had a sensitivity of 69%, allowing appropriate planning of fetal surveillance and timing and method of delivery for most patients. No false-positive diagnoses led to inappropriate perinatal management.

The low overall sensitivity of prenatal ultrasonographic examinations in this study may be attributed to poor detection of cardiovascular anomalies, the second most common group of malformations. As are other anomalies, cardiovascular malformations are as much as twice as common among twins as among singletons. Since these cardiac structural defects are frequently of great physiologic significance, adequate screening for them is important. Although detailed

echocardiography has been reported as beneficial for some groups specifically at increased risks for fetal cardiac anomalies,9 a basic ultrasonographic examination with a four-chamber cardiac view, as performed in this study, generally has been regarded as an adequate screen. Copel et al.10 reported a 92% sensitivity for the detection of cardiac structural defects using the fourchamber view as the primary screening technique. They attributed the imperfect sensitivity to difficulties in detecting uncomplicated ventricular septal defect, semilunar valve stenosis, coarctation of the aorta, and simple transposition. Of those lesions potentially missed with a four-chamber view, only simple ventricular septal defect is specifically noted to be more common in twins.5 A false-negative four-chamber cardiac ultrasonographic examination for simple ventricular septal defect will not alter perinatal outcome, but missing a malformation of greater physiologic significance, such as pulmonary stenosis, may indeed have a negative impact on perinatal outcome. Given the increased risk of

^{*}Number diagnosed prenatally per number diagnosable prenatally.

cardiac structural defects in twins and the insensitivity of the routine four-chamber cardiac view for some of the malformations, echocardiographic evaluation of the aortic and pulmonary outflow tracts, the arch of the aorta, and ventricular size could increase the sensitivity of the screening protocol.

The genitourinary system demonstrated the highest incidence of structural anomalies among twins in this study, yet prenatal diagnosis would be neither expected nor helpful in perinatal management in nearly half of these abnormalities (hypospadias and inguinal hernia). Prenatal ultrasonography did detect 86% (6/7) of the genitourinary lesions for which perinatal management might be altered.

The increased risk for congenital anomalies among twins has been reported as limited to those of the same sex3.4 and, more specifically, monozygotic twins.5 Single members of five monozygotic twin pairs were affected by congenital anomalies, including nonimmune hydrops (in association with twin-twin transfusion), hydronephrosis, hypospadias, and hydrocele. An undefined subset of 12 dichorionic same-sex twin pairs with at least one malformed member also may have been monozygotic. On comparison of the proportion of monozygotic congenitally malformed twins in this study (≥15%) with the similar proportion of monozygotic twins in the general twin population (approximately 20%), we cannot confirm an increased incidence of congenital malformations in monozygotic twins. Concordance for abnormalities also has been reported as higher among same-sex twins3 and monozygotic twins.5 Six of the 28 (21%) major congenital anomalies occurred concordantly in three twin pairs, including one quarter (4/16) of those major anomalies for which prenatal care may be altered. This suggests that the identification of a major congenital anomaly in one twin of a same-sex set should prompt a careful search, particularly for a related anomaly, in the other twin.

Although recommended for the sequential assessment of growth, serial anatomic surveys also proved useful for prenatal diagnosis of malformations in this study. After a prior normal second-trimester sonogram, hydronephrosis was first detected in one fetus during a third-trimester scan.

Even a single occurrence of some of the abnormalities included in a study of this size yields an incidence greater than that reported elsewhere for either single or multiple gestations. The limited sample size also may explain the absence of some congenital abnormalities reported to be more common among twins, such as neural tube defects and facial clefts.5 Limitations attributable to the sample size of this study are recognized; the purpose of our study is to assess the accuracy of ultrasonographic prenatal diagnosis in twins, not to define the scope of malformations in this population.

We conclude that serial prenatal ultrasonographic examinations that include a basic anatomic survey are useful in detecting the noncardiac anomalies for which twins are at increased risk but that the four-chamber cardiac view in not an adequate screen for cardiac structural malformations of twins.

We recognize the assistance of Reem Abu-Rustum in data collection.

Does amniotic fluid index affect the accuracy of estimated fetal weight in preterm premature rupture of membranes?

Julianne S. Toohey, MD, David F. Lewis, MD, James A. Harding, MD, Michael Crade, MD, Tamerou Asrat, MD, Carol A. Major, MD, Thomas J. Garite, MD, and Manuel Porto, MD

Orange and Long Beach, California

Estimated fetal weights play a critical role in the management scheme of patients with preterm premature rupture of membranes but are often technically difficult to obtain in these patients because of low amniotic fluid volume. Previous studies have had conflicting data as to the accuracy of estimated fetal weights in preterm premature rupture of membranes. This study was undertaken to evaluate the effect of amniotic fluid index on the accuracy of estimated fetal weights in pregnancies complicated by preterm premature rupture of membranes. Over a 2-year period at Long Beach Memorial Medical Center, 98 patients with preterm premature rupture of membranes who had an ultrasonographic examination with estimated fetal weights and amniotic fluid index performed within 48 hours of delivery were identified and compared with a control group of 55 patients in preterm labor with normal amniotic fluid index for gestational age, also obtained within 48 hours of delivery. Shepard and Hadlock formulas were used to estimate fetal weight. Results were measured in percent error from the actual birth weight. All birth weights were <2000 gm. No statistical differences were identified. The value of amniotic fluid index did not affect the accuracy of predicted estimated fetal weight in preterm premature rupture of membranes. Predicted estimated fetal weight of patients with preterm premature rupture of membranes appears to be as accurate as predicted estimated fetal weight in pregnancies with normal amniotic fluid volumes. (AM J OBSTET GYNECOL. 1991;165:1060-2.)

premature rupture of membranes. Previous studies have had conflicting reports regarding the reliability of estimated fetal weight, leaving the obstetrician unsure of the usefulness of these data. It has been suggested that low amniotic fluid volume leads to compression of the head and abdomen, in addition to reducing the resolution of the ultrasonographic image, rendering the estimated fetal weight inaccurate and unreliable.^{1,2}

No previous study has evaluated the effect of accuracy of estimated fetal weights and how this correlated

with amniotic fluid index in pregnancies complicated by preterm premature rupture of membranes. This study was designed to evaluate the effect of oligohydramnios on the accuracy of estimated fetal weights in pregnancies complicated by preterm premature rupture of membranes.

Material and methods

Medical records of 98 patients delivered at Long Beach Memorial Women's Medical Center with the diagnosis of preterm premature rupture of membranes and birth weights of <2000 gm were retrospectively analyzed. Preterm premature rupture of membranes was defined as rupture of membranes occurring before 36 weeks. It was confirmed in all patients by sterile speculum examination with pooled fluid, ferning, and alkaline pH determinations (Nitrazine test). All ultrasonographic measurements and evaluations were performed by the perinatal staff within 48 hours of delivery.

Amniotic fluid indexes were determined by the fourquadrant technique, as described by Phelan et al.3 Patients were stratified into four groups according to the degree of oligohydramnios detected. Estimated fetal weights were calculated by using Shepard et al.4 (biparietal diameter, abdominal circumference) and Hadlock et al.5 (femur length, abdominal circumference) formulas.

The control group, matched for gestational age and birth weight, consisted of 55 patients in preterm labor with intact membranes and normal amniotic fluid index for gestational age. Ultrasonographic examinations also were performed in the control group within 48 hours of delivery and by the same perinatal staff.

Power analysis predicted an 80% chance of detecting a 30% difference in the percent error from actual birth weight in a total population of 98 patients. Data were analyzed with the Wilcoxon rank sum test with a p value < 0.05 considered statistically significant. All comparisons were against a two-sided alternative hypothesis expressed as percent error ± 1 SD from actual birth weight.

Results

Table I depicts the effect of amniotic fluid index measurements on the accuracy of predicted estimated fetal weight assessed as percent error of estimated fetal weight from actual birth weights, with the Shepard formula. Table II describes the same relationship with the Hadlock formula. The patients were grouped with regard to degree of oligohydramnios, with 43 noted to have an amniotic fluid index between 0.0 and 5.0. Not depicted in the table are 19 of these 43 patients who were determined to have severe oligohydramnios with an amniotic fluid index between 0.0 and 2.0. Twentynine patients had an amniotic fluid index between 5.9

Table I. Estimated fetal weight with the Shepard formula

Amniotic fluid index (cm)	No.	Estimated , fetal weight*	
0.0-5.0	43	9.42 ± 7.2	
5.1 - 9.9	29	8.57 ± 6.7	
>10	26	10.12 ± 8.5	
Control	55	9.65 ± 8.5	

^{*}Percent error ± SD.

Table II. Estimated fetal weight with the Hadlock formula

F	Amniotic fluid index (cm)	No.	Estimated fetal weight*	
	0.0-5.0	43	9.15 ± 7.2	
	5.1-9.9	29	9.87 ± 6.9	
	>10	26	12.18 ± 10.7	
	Control	55	10.88 ± 8.8	

^{*}Percent error ± SD.

Table III. Correlation of birth weight and estimated fetal weight in preterm premature rupture of membranes

Birth weight (gm)	No.	Shepard*	Hadlock*
500-1000	35	9.65 ± 8.5	11.15 ± 9.9
1001-1500	27	9.27 ± 6.7	10.74 ± 8.2
1501-2000	36	9.40 ± 6.6	9.47 ± 6.6

^{*}Percent error ± SD.

and 9.9, and 26 patients were determined to have fluid indexes of >10. No statistical difference was noted in percent error between the study patients with preterm premature rupture of membranes and the control group with intact membranes, or between the subgroups of amniotic fluid volume. In addition, there were no statistical differences in the percent error calculated by either formula.

Patients also were stratified with regard to birth weight, with 35 infants weighing between 500 and 1000 gm. As depicted in Table III, both formulas appear to be equivalent in their ability to predict estimated fetal weight with varying birth weights, even when addressing the very-low-birth-weight groups.

Comment

Estimation of fetal weight plays a critical role in the decision-making and management scheme of patients with preterm premature rupture of membranes. However, the literature addressing the issue of accuracy of estimated fetal weight in the face of oligohydramnios remains confusing and sparse. All the studies examining estimated fetal weight in patients with preterm premature rupture of membranes published to date lack a concise and quantifiable definition of oligohydramnios and "low fluid volume," rendering the data difficult to interpret.

In 1985, O'Keefe et al.¹ were the first authors to report that biparietal diameter measurements in patients with preterm premature rupture of membranes were inaccurate in 45% of their 100 patients as assessed by an abnormal cephalic index and concluded that biparietal diameter measurements were unreliable in estimating fetal weight in patients with preterm premature rupture of membranes.

This study did not quantify or justify the severity of oligohydramnios that resulted in distortion of the contour of the head. In 1986 a similar study looking at the effects of oligohydramnios on estimation of fetal weight by Ott et al.2 concluded that the cephalic index was not appreciably distorted by oligohydramnios. Again, that study did not define the degree of oligohydramnios observed in study patients. Subsequently, Bottoms et al.6 reported an estimation of fetal weight in 26 pregnancies complicated by premature rupture of the membranes. Although all measurements were smaller in patients with premature rupture of the membrane than in control patients, the authors attributed this finding to compromised intrauterine growth rather than artifacts from physical compression caused by oligohydramnios.

Benacerraf et al.⁷ in 1988 looked at the accuracy of ultrasonographically estimated fetal weight in a large series of 1301 patients with varying amounts of amniotic fluid volume and noted that the presence of oligohydramnios made no difference in the percent errors. In this study 17% were noted subjectively to have oligohydramnios and only 20 of 1301 fetuses had birth weights <2000 gm.

Townsend et al.⁸ in 1988 looked specifically at ultrasonographically estimated fetal weight in 53 very-low-birth-weight infants (<1000 gm). Twenty-four fetuses were noted to have "decreased" amniotic fluid volume subjectively. The authors reported that no statistical differences in accuracy of weight prediction in preterm deliveries were observed when patients with normal amniotic fluid were compared with those with oligohydramnios. Finally, in 1990 Valea et al.⁹ compared 86 patients with preterm premature rupture of membranes at ≤36 weeks with 112 control patients with intact membranes matched for gestational age and were able to demonstrate that amniotic fluid volume was not an important variable in the accuracy of ultrasono-

graphically estimated fetal weights. However, in this study there was no mention of the percentage of patients with oligohydramnios, and the amniotic fluid was not quantified.

In our study we quantified the degree of oligohydramnios and demonstrated in support of the cited studies that low amniotic volumes do not appreciably affect the accuracy of ultrasonographically estimated fetal weights in patients with preterm premature rupture of membranes. Nineteen of our study patients had severe oligohydramnios with an amniotic fluid index of 0 to 2 cm. In spite of this severe lack of fluid, the percent error from actual birth weight was only 7.45 ± 7.2 by the Shepard formula and 9.15 ± 7.2 by the Hadlock formula. Predicted estimated fetal weights in preterm gestations with preterm premature rupture of membranes appear to be as accurate as those predicted in patients with normal amniotic fluid volume, even in very-low-birth-weight infants.

We conclude that, in the hands of experienced ultrasonographers, predicted estimated fetal weights may be used with confidence in the management of pregnant patients with oligohydramnios.

Transcervical chorionic villus sampling and midtrimester oligohydramnios

Edith Y. Cheng, MD, David A. Luthy, MD, Durlin E. Hickok, MD, B Kathryn A. Hollenbach, PhD, Bobert G. Resta, MS, Barry S. Mahony, MD, and Frederick W. Luthardt, PhD

Seattle, Washington

To study the possible association between transcervical chorionic villus sampling and midtrimester oligohydramnios, we conducted a prospective cohort study of all women who were seen for genetic counseling in the first trimester during a 2-year period. Women who chose chorionic villus sampling were compared with women who chose traditional amniocentesis for incidence of midtrimester oligohydramnios. Of 442 women exposed to chorionic villus sampling with a normal fetal karyotype, severe oligonydramnios developed in 12 (2.7%) at 16 to 23 weeks' gestation. None of the 391 women with normal fetal karyotypes who were counseled at the same time in pregnancy but who chose amniocentesis had oligohydramnios at the time of amniocentesis (p = 0.01). A nested case-control analysis was performed within the chorionic villus sampling group to evaluate risk factors associated with midtrimester oligohydramnios. Midtrimester oligohydramnios occurring after chorionic villus sampling was associated with postprocedure bleeding and elevated maternal serum α -fetoprotein (p < 0.01). There were no perinatal survivors with midtrimester oligohydramnios. (Am J OBSTET GYNECOL 1991;165:1063-8.)

Key words: Chorionic villus sampling, amniocentesis, oligohydramnios

First-trimester transcervical chorionic villus sampling is now widely available for early prenatal diagnosis of chromosomal and metabolic abnormalities. Pregnancy loss after this procedure is reported to be 2% to 5%.1-6 The pregnancy loss rate after midtrimester amniocentesis is reported to be 0.5% to 1.0%.7-8

It has been suggested that midtrimester oligohydramnios may be a late complication of chorionic villus sampling,3,9 although this assertion has not been systematically evaluated. In fact, the exact frequency of midtrimester oligohydramnios remains uncertain. Several studies 10-12 have addressed the poor prognosis of midtrimester oligohydramnios and its association with fetal abnormalities, but descriptive data on the prevalence of midtrimester oligohydramnios in the population are generally lacking.

To study the possible association between transcervical chorionic villus sampling and midtrimester oligohydramnios, we conducted a prospective cohort

seling in the first trimester during a 2-year period. Women selecting chorionic villus sampling were compared with those women selecting traditional amniocentesis for the occurrence of midtrimester oligohydramnios. A separate cohort of women not seen until the midtrimester for amniocentesis were studied during the same time period to estimate a population prevalence of midtrimester oligohydramnios.

study of all women who were seen for genetic coun-

Material and methods

The study population consisted of all women referred for genetic counseling during the first trimester at Swedish Hospital Medical Center, Seattle, Washington, between Jan. 1, 1988, and Dec. 31, 1989, inclusive.

Patients were seen at 6 to 11 weeks from the last menstrual period and underwent an ultrasonographic examination on the initial visit for confirmation of fetal viability and for ascertainment of gestational age. Patients also received counseling regarding chorionic villus sampling and amniocentesis, with the choice of procedure left to the patient. Patients electing chorionic villus sampling were scheduled for the procedure at 9 to 12 weeks (menstrual), and those patients electing amniocentesis (amniocentesis group A) were scheduled for the procedure at 15 to 20 weeks.

Exclusion criteria for chorionic villus sampling included active vaginal infection (herpes, streptococcus, yeast), twins, severely retroverted uterus, or vaginal bleeding—either clinically within 1 week of procedure or as a perigestational hemorrhage seen on ultrasonography at the time of scheduled procedure. These patients were scheduled for amniocentesis at 15 to 20 weeks.

Before the chorionic villus sampling procedure, an ultrasonographic examination was performed to determine uterine position, placental location, and gestational age. After sterile cervical preparation, chorionic villus sampling was performed by one of two obstetricians using a 5.7 Fr Cook chorionic villus sampling catheter under continuous ultrasonographic observation. Up to three separate attempts were performed (separate catheter with each attempt) to obtain adequate villi (approximately 10 mg). The procedure was terminated as soon as adequate villi were obtained. Patients were seen at 24 to 48 hours after procedure for confirmation of fetal viability by ultrasonography and for assessment of amniotic fluid volume and interval complications, such as bleeding, uterine cramping, leakage of amniotic fluid, or fever. At 15 to 20 weeks patients had a maternal serum α-fetoprotein (AFP) assay and a complete ultrasonographic examination to assess interval growth, amniotic fluid volume, and fetal anomalies. Pregnancy outcome data were obtained on all patients.

Patients electing amniocentesis (amniocentesis group A) were scheduled for the procedure at 15 to 20 menstrual weeks. Before the procedure, a complete ultrasonographic examination was repeated to assess interval growth (from 6 to 11 weeks before counseling ultrasonography), placental location, amniotic fluid volume, and fetal anomalies. Amniocentesis was performed by one of four obstetricians, using a 22-gauge spinal needle under continuous ultrasonographic guidance. Twenty-five milliliters of amniotic fluid was withdrawn for fetal karyotype and amniotic fluid AFP assay. Pregnancy outcome data were obtained from existing follow-up protocols in place since 1973, which call for telephone and letter contact by both referring physician and patient for any untoward pregnancy outcome after amniocentesis. This group served as the control group to compare risks of midtrimester oligohydramnios with the chorionic villus sampling group.

A separate cohort of women, amniocentesis group B, was used to assess the baseline prevalence of oligohydramnios in the midtrimester. This cohort consisted of all women seen during the study period for amniocentesis in the midtrimester because of advanced maternal age or prior fetal chromosome anomaly only. Multiple gestation and high and low maternal serum AFP cases were excluded. The protocol followed with this group was identical to that followed by the amniocentesis group A.

The genetic counseling and hospital medical records of all study participants were reviewed for information pertaining to the procedure chosen, procedural complications and results, pregnancy outcome, and demographic characteristics. Cases with abnormal karyotypes and recognizable fetal malformations were excluded from further analysis. For the purposes of this study, oligohydramnios was defined as decreased amniotic fluid observed on ultrasonography with the deepest pocket of amniotic fluid being ≤1 cm in depth.

Initial comparisons on the occurrence of midtrimester oligohydramnios were made with Fisher's exact test between midtrimester ultrasonographic examinations of women exposed to first-trimester chorionic villus sampling and women undergoing first-trimester ultrasonography and counseling for chorionic villus sampling but who elected midtrimester amniocentesis (amniocentesis group A).

A nested case-control analysis was conducted on all women who elected to have chorionic villus sampling. Cases of oligohydramnios detected between 16 and 20 weeks' gestation were compared with controls with normal amniotic fluid volume levels during the same time period. Comparisons between cases and controls were made with Fisher's exact and t tests for maternal characteristics, amount of villi sampled, number of catheter insertions, operator, procedural complications, chorionic villus sampling results, elevated maternal serum AFP, pregnancy complications, and pregnancy outcome. To control for the potentially confounding effect of abnormal karyotype, the analysis also was conducted after all women with abnormal chorionic villus sampling results were excluded. To assess possible clustering of oligohydramnios cases, the study period was divided into quartiles, and the χ^2 test for trend was performed.

Results

A total of 872 women received first-trimester counseling and selected a prenatal diagnosis procedure during the study period. Of these, 477 women chose chorionic villus sampling and 395 chose amniocentesis (amniocentesis group A) (Table I). Women who chose chorionic villus sampling were slightly older than women who selected amniocentesis but did not differ on indications for procedures. Women who underwent chorionic villus sampling were more likely to have bleeding after the procedure and were more likely to have abnormal results than were women who underwent amniocentesis. The number of women who selected neither procedure or who spontaneously aborted after counseling but before either chorionic villus sampling or midtrimester amniocentesis cannot be ascertained through the data set.

There were an additional 2664 women who were seen for amniocentesis in the midtrimester (amniocentesis group B). Their profiles were similar to those of the amniocentesis group A.

Biochemical and chromosomal abnormalities and pregnancy losses to 28 weeks are presented by procedure in Table II. The chorionic villus sampling group had higher rates of spontaneous abortion, midtrimester oligohydramnios, chromosomal anomalies, and metabolic disorders than did either amniocentesis group.

There were three cases of midtrimester oligohydramnios noted among the 2664 women in the amniocentesis group B (0.1%). Two of these cases were associated with chromosomal anomalies (triploidy). Thus, when corrected for chromosomal abnormalities, there was one case of oligohydramnios among 2615 women (0.04%).

In 12 of 442 women (2.7%) with a normal fetal karyotype who underwent chorionic villus sampling, oligohydramnios developed at 16 to 23 weeks compared with none of 391 women with a normal fetal karyotype who were counseled at the same time in pregnancy but elected midtrimester amniocentesis (p = 0.01) (Table III). The differences also were statistically significant when analyzed at 16 to 20 weeks and 20.1 to 23 weeks.

Characteristics of the women undergoing chorionic villus sampling by oligohydramnios status are presented in Tables IV and V. There were no significant differences between these two groups in maternal age, gravidity, parity, number of attempts at chorionic villus sampling, mean gestational age at the time of procedure, or mean amount of villi sampled. Additionally, there was no difference in the prevalence of oligohydramnios between the operators, and the oligohydramnios cases occurred evenly over the study period and were not clustered in any quartile.

Forty-two percent of the women whose pregnancies were complicated by oligohydramnios after chorionic villus sampling experienced bleeding immediately after the procedure, as compared with 8.8% of those with normal amniotic fluid (p < 0.01). Women with oligohydramnios also were more likely to have a maternal serum AFP ≥2.5 multiples of the normal median when compared with those with normal amniotic fluid volume, 16.5% and 1.5%, respectively (p < 0.01). When the analysis was restricted to women at 16 to 20 weeks with normal chorionic villus sampling results, these differences remained significant. Sixty percent of the women with oligohydramnios (3 of 5) had bleeding immediately after chorionic villus sampling, as compared with 9.5% (41 of 435) of those with normal fluid (p < 0.01). Similarly, 40% of the women (2 of 5) with oligohydramnios had elevated maternal serum AFP (>2.5) as compared with 1.6% (7 of 435) of controls with normal fluid volume (p < 0.01).

There were no perinatal survivors among the 12 pregnancies with midtrimester oligohydramnios. The case summaries and pregnancy outcomes are shown in Table VI.

Comment

Although midtrimester oligohydramnios has been suggested as a complication of chorionic villus sampling,^{8, 9} this has not been systematically evaluated or adequately addressed in the chorionic villus sampling studies to date. We observed midtrimester oligohydramnios in 12 of 442 (2.7%) chromosomally normal pregnancies that experienced chorionic villus sampling compared with 0 of 391 controls who elected amniocentesis-a marked difference. Women who chose chorionic villus sampling were slightly older than controls, but this has been noted in other studies.1,2 Women who chose chorionic villus sampling were more likely to have abnormal results, mostly related to a higher percentage of biochemical indications and to the earlier gestational age at the procedure. They were also more likely to experience after the procedure vaginal bleeding. We observed a higher rate of spontaneous abortion among women who chose chorionic villus sampling than among those who chose amniocentesis, but these rates are not comparable. In our data set we can-

not identify the number of patients aborting or lost to follow-up after first-trimester counseling but before second-trimester amniocentesis.

Midtrimester oligohydramnios most often occurs with fetal anomalies, either renal or chromosomal, and is extremely rare in otherwise normal gestations. ¹⁰⁻¹² Only one case was observed among 2615 chromosomally normal gestations (0.04%) in amniocentesis group B. The true prevalence could be significantly less than that.

There are at least three potential explanations for the observed differences in oligohydramnios between the two groups. First is the so-called learning curve, which states that complications are highest as new procedures are learned and then decrease as experience is gained. This has been suggested as a reason for increased spontaneous abortion rates among new chorionic villus sampling centers.^{3, 9}

The learning curve effect is supposedly dampened as procedures become more widespread and one learns from the mistakes of others. If the learning curve were a factor, an increased number of catheter insertions, decreased tissue volume, or clustering, either by physician or in any quartile of the study period, might be expected. However, as seen in Tables IV and V, there were no differences in these variables between groups.

It also has been further suggested that midtrimester oligohydramnios could result from the chorionic villus sampling catheter indenting the gestational sac, thus causing a disruption. Gestational sac indentation at the time of the procedure was not observed in any of the cases of oligohydramnios in the present series.

A second explanation might be chorionic villus sampling catheter size. The Cook catheter, which measures 5.7 Fr or 20 mm external diameter, was used in the present study. The Portex catheter, the other major chorionic villus sampling catheter, measures 18 mm

external diameter. Most series of chorionic villus sampling data presented to date have used the Portex catheter. The larger catheter size could potentially be related to oligohydramnios, but tissue volumes obtained in this study were similar to those obtained in other studies^{1,5} using other catheters.

A third explanation for the observed differences would be underreporting of oligohydramnios. Without a very careful follow-up protocol that called specifically for midtrimester ultrasonography, several cases of oligohydramnios might have been overlooked. Six of the 12 cases presented as intrauterine fetal deaths and two additional cases had premature rupture of the membranes and spontaneous abortion. Thus two thirds of the cases of midtrimester oligohydramnios could have been missed without careful surveillance. Other studies also have noted late pregnancy losses after chorionic villus sampling that may be associated with oligohydramnios.^{2, 3}

We believe the most likely explanation is that cho-

rionic villus sampling may cause a placental or endometrial injury that may result in perigestational hemorrhage. These changes may result in severely altered fetoplacental perfusion and, over time, midtrimester oligohydramnios. Oligohydramnios was associated with postprocedural bleeding and elevated maternal serum AFP in the midtrimester, both consistent with placental injury. The association with elevated maternal serum AFP may be even stronger than we observed. One half of the cases of oligohydramnios did not have maternal serum AFP determined, presumably because of midtrimester intrauterine fetal death recognized before scheduled blood drawing.

The prognosis for midtrimester oligohydramnios is grim. There were no survivors among the 12 cases. Only three of 12 (25%) achieved 26 weeks' gestation. These three infants all died, two shortly after delivery and the third at 9 months of age, having never left the neonatal intensive care unit.

Our study suggests that first-trimester transcervical

chorionic villus sampling may be associated with an increased risk for midtrimester oligohydramnios and its grim prognosis. Future studies of chorionic villus sampling should be designed to address this issue, and midtrimester ultrasonography should be considered in women who undergo chorionic villus sampling.

Intrapartum course of fetuses with isolated hypoplastic left heart syndrome

G. Marc Jackson, MD, Jack Ludmir, MD, Arthur J. Castelbaum, MD, James C. Huhta, MD, and Arnold W. Cohen, MD

Philadelphia, Pennsylvania

Once considered universally fatal, the hypoplastic left heart syndrome is now being surgically treated in the newborn period. To help formulate an appropriate management plan for the labor and delivery of these patients, we reviewed the intrapartum course and immediate neonatal outcome of 13 fetuses with known hypoplastic left heart syndrome. Eleven of 13 patients underwent labor, and only one had an abnormal fetal heart rate pattern. There were no cases with meconium staining of the amniotic fluid. All patients with spontaneous or induced labor were delivered vaginally. There were no Apgar scores <8 at 5 minutes, and all umbilical cord blood pH values were ≥7.20. All infants survived to undergo initial reconstructive surgery. We conclude that labor does not appear to be a high-risk situation for the fetus with this disorder. Routine intrapartum fetal heart rate monitoring can be used, oxytocin can be used as indicated, and cesarean section should be reserved for traditional obstetric indications. (AM J OBSTET GYNECOL 1991; 165:1068-72.)

With improved imaging technology and increased use of obstetric ultrasonography, prenatal identification of congenital heart disease is increasing in frequency. At the same time advancements in pediatric cardiac surgery have improved the long-term outlook for many newborns with structural heart defects. Perhaps most dramatically, neonates with left ventricular outflow tract obstruction caused by the hypoplastic left heart syndrome, once considered a universally fatal condition, are now being successfully treated with both reconstructive surgery1 and transplantation.2 In general, newborns with this syndrome are considered to be candidates for surgical treatment if no other significant structural abnormalities are present, the infant has a normal karyotype, and there is no evidence of cardiac failure. The reconstructive surgical technique is a multistage procedure, currently with a 61% 1-year survival after the first palliative procedure and a 40% overall long-term survival after the second reconstructive surgery.3 The present actuarial 3-year survival after cardiac transplantation therapy for hypoplastic left heart syndrome is reported to be 80%.4

Knowledge of an abnormal fetal condition can significantly alter the management scheme for pregnancy and delivery. While some data exist regarding the natural history of hypoplastic left heart syndrome in the fetal and newborn periods, little information is available on the behavior of these fetuses during labor and delivery.5, 6 To help formulate an appropriate intrapartum management plan for the patient with a fetus that is a potential candidate for repair of critical left ventricular outflow tract obstruction, we reviewed the course of labor and immediate neonatal outcome of 13 such patients referred to our center for obstetric and neonatal care.

Material and methods

The prenatal office and hospital charts, including the complete intrapartum fetal heart rate (FHR) monitor tracings, were available for review for 13 fetuses with the antenatal diagnosis of isolated hypoplastic left heart syndrome who were transferred to our institution for obstetric and neonatal management between May 1986 and August 1990. All fetuses were considered to be candidates for neonatal surgical repair; all were free of other structural malformations, had a normal karyotype, and had no ultrasonographic evidence of heart failure. Fetuses who failed to meet these criteria were not considered appropriate surgical candidates and were not accepted in transfer for antenatal management. In each of the 13 cases the identification of structural heart disease was made by the referring physician; the diagnosis of hypoplastic left heart syndrome was verified by a pediatric cardiologist (J.C.H.) after maternal transport with two-dimensional Doppler echocardiography. Antepartum and intrapartum care was provided by a team of perinatologists and obstetric residents. Patients in labor had continuous electronic fetal monitoring, and those who underwent elective cesarean delivery were monitored for at least 30 minutes before establishment of anesthesia. Apgar scores were assigned by pediatricians in the delivery room. Umbilical cord blood pH was measured in 10 of the 13 cases. Two-dimensional Doppler echocardiography was repeated in the immediate neonatal period for diagnostic confirmation. All FHR tracings were reviewed by three of the authors (G.M.J., J.L., A.J.C.) without knowledge of fetal intrapartum course or outcome, and standard criteria were used to interpret the FHR patterns.7

Results

The antenatal identification of hypoplastic left heart syndrome was made at least 2 weeks before delivery in each case, at a mean gestational age of 25 weeks. All 13 of the fetuses were diagnosed as having the hypoplastic left heart syndrome, each had a normal karyotype demonstrated by analysis of either cultured amniocytes or fetal lymphocytes, and none had any ultrasonographic evidence of other major structural malformations or hydrops fetalis.

The average gestational age at delivery was 38.8 weeks (range, 34.5 to 41.5 weeks). Eleven infants (85%) were delivered after 37 completed weeks, one child was delivered at 36 weeks after a pregnancy complicated by premature labor, and one child was delivered at 34.5 weeks because of active labor with a previous classic cesarean section.

All fetuses were in cephalic presentation at the time of onset of labor or planned delivery. Labor was spontaneous in five patients (38%) and electively induced in six (46%). A scheduled repeat cesarean section was performed in one patient (8%), and another cesarean section was performed in a patient in active labor who was not considered a candidate for labor because of a previous vertical uterine incision. Of the five patients with spontaneous labor, one (20%) required oxytocin augmentation. All labor inductions were elective and initiated with oxytocin infusion; because of cervical status, preinduction cervical ripening with prostaglandin gel was not necessary in any instance. All patients with spontaneous or induced labor were delivered vaginally. There was only one operative vaginal delivery, a low vacuum extraction after maternal exhaustion in the second stage of labor.

Of the 11 laboring patients, three had external electronic fetal monitoring only and eight had fetal scalp electrodes applied. Each of the 11 fetuses had a normal baseline FHR, and 10 (91%) had FHR reactivity. No fetal dysrhythmias were noted. Mild or moderate variable decelerations were noted at some point during labor in six cases (55%), and recurrent late decelerations were seen in only one (9%) who had a normal scalp pH (7.31). No fetus manifested severe variable FHR decelerations, and there was no meconium staining of amniotic fluid in any case.

Seven laboring patients underwent epidural anesthesia, and four tolerated labor without analgesia. Two of the patients without epidural anesthesia had local perineal anesthesia for delivery. Both cesarean sections were performed with the patients under regional anesthesia, one spinal and one epidural. There were no anesthesia-related complications.

The range of birth weights was 2180 to 4110 gm (mean, 3042 ± 652). Twelve of the 13 infants had 1-minute Apgar scores ≥ 7 , and all 13 had 5-minute Apgar score of 4, with a 5-minute score of 8 and a venous cord blood pH of 7.36 after an uneventful vaginal delivery. All umbilical cord arterial blood pH values were ≥ 7.20 , and all venous samples had a pH ≥ 7.26 .

All newborns were admitted directly to the neonatal intensive care nursery, and an intravenous infusion of prostaglandin E₁ was started, with elective ventilatory control of acid-base balance used as indicated. All 13 neonates had the diagnosis of hypoplastic left heart syndrome confirmed on the first day of life. Surgical repair was planned for all of the infants in this series, as cardiac transplantation was not available in our center at that time. All of the infants survived to stage I surgical reconstruction, performed between the first and nineteenth day of life (mean, fifth day of life).

Comment

The hypoplastic left heart syndrome is a group of structural cardiac malformations with a hypoplastic or absent left ventricle, a stenotic, hypoplastic, or atretic aortic valve, and a hypoplastic ascending aorta. Approximately 85% of cases have an associated mitral underdevelopment, while the remaining 15% have a common atrioventricular canal with a misalignment of the ventricular septum giving predominance to the right ventricle. Estimated to occur once in every 3000 to 6000 live births, hypoplastic left heart syndrome accounts for approximately 5% to 10% of congenital heart disease and has been cited as the most frequent cause of death from congenital cardiac disease in the first week of life.

The underlying etiology of hypoplastic left heart syndrome is poorly understood, but the fundamental defect is thought to involve interruption of blood flow through the left ventricle, with restriction of either inflow or outflow.8 When not associated with a specific syndrome or chromosomal abnormality, hypoplastic left heart syndrome has traditionally been believed to be multifactorially inherited,8 with an empiric recurrence risk of 0.5% to 2%.11 More recent data challenge the idea of multifactorial inheritance and suggest a much higher incidence of cardiac malformations in first-degree relatives of children affected with hypoplastic left heart syndrome. An evaluation of the siblings of 50 infants with isolated hypoplastic left heart syndrome revealed congenital structural heart disease in 13.5%.12 All of the identified defects were etiologically related to hypoplastic left heart syndrome, being associated with abnormal embryonic blood flow (hypoplastic left heart syndrome, coarctation of the aorta, perimembranous ventricular septal defect). As the multifactorial model does not seem to fully explain the inheritance of isolated hypoplastic left heart syndrome and related malformations, it has been proposed that hypoplastic left heart syndrome is inherited in an autosomal recessive fashion. While simple mendelian inheritance seems improbable, it cannot be statistically rejected on the basis of the available data. 8, 12

The unique physiologic characteristics of hypoplastic left heart syndrome are a consequence of the abnormal anatomy. In utero, blood entering the left atrium is shunted to the right atrium through the foramen ovale. The right ventricle, then, supports the systemic circulation through the ductus arteriosus communicating with the descending aorta. In most cases, right ventricular output is adequate for normal fetal growth. After birth, however, hypoplastic left heart syndrome is said to be a ductal-dependent malformation; that is, systemic perfusion in the newborn period requires atrial left-to-right shunting of oxygenated blood with a patent ductus arteriosus providing a conduit for right ventricular output to reach the aorta. Nearly all infants appear normal until the time of physiologic closure of the ductus, at which time systemic blood flow is interrupted. The timing of the subsequent decompensation with shock and metabolic acidosis is variable but the decompensation usually takes place by the third day of postnatal life. Continued hypoperfusion and worsening acidosis ultimately result in death, which occurs in the first month of life in more than 60% of untreated neonates, with fewer than 5% surviving 1 year. 10, 14

For newborns with hypoplastic left heart syndrome who are candidates for surgical treatment, clinical stabilization requires maintenance of a patent ductus arteriosus and a careful balance between systemic and pulmonary resistance. Ductal patency is most often preserved with a continuous intravenous infusion of prostaglandin E₁. Because ductal closure is a gradual process and does not occur immediately at the time of birth, the prostaglandin infusion need not be initiated in the delivery room but should be started within the first hour or so of life. Elective intubation and paralysis can be used to mechanically hypoventilate these newborns, as a Pco2 of 45 to 50 mm Hg results in an elevated pulmonary resistance, lowered systemic resistance, and improved peripheral perfusion. Mild hypoxia is well tolerated, whereas hyperoxia is to be avoided because of untoward effects on peripheral resistance.3,4

In the fetus with hypoplastic left heart syndrome, real-time ultrasonographic imaging of the heart in the plane of the four-chambered view fails to show the apex of both ventricles at the same level.¹⁵ Confirmation of

the diagnosis in utero requires two-dimensional Doppler echocardiography to completely define the constellation of abnormal findings. In the newborn, qualitative assessment of chamber and vessel location and size are important in affirming the presence of hypoplastic left heart syndrome, and quantitative measurements of left ventricle chamber size have been shown to be predictive of outcome with conditions of severe left ventricular outflow tract obstruction.16 Not only can two-dimensional echocardiography confirm the diagnosis of hypoplastic left heart syndrome, but a complete delineation of cardiac and vascular anatomy is possible. Diagnostic cardiac catheterization was not necessary before surgery in any of our cases, consistent with the experience in other centers.17

Approximately one third of newborns with hypoplastic left heart syndrome have an associated chromosomal abnormality, genetic defect, or major extracardiac structural malformation.9, 14 Chromosomal aneuploidies, most commonly trisomy 18, trisomy 13, trisomy 21, and monosomy X, have been reported in 4% to 11% of cases of hypoplastic left heart syndrome. Additionally, it is seen with a number of other genetic disorders (both autosomal recessive and dominant) and malformation syndromes such as the DiGeorge sequence and the VATER (vertebral defects, imperforate anus, tracheoesophagal fistula, and radial and renal dysplasia) association. Even in the absence of a chromosomal abnormality or malformation complex, the incidence of noncardiac structural malformations concurrent with hypoplastic left heart syndrome is approximately 10%.18-20 Although rare, nonimmune hydrops fetalis has been reported with hypoplastic left heart syndrome²¹⁻²³; structural heart disease with fetal hydrops is a very poor prognostic sign, with nearly universal mortality in some series.23

It should be stressed that our patients represent a highly selected group. All had the diagnosis of a specific congenital heart malformation made in utero and had follow-up in a high-risk setting with an assiduous search made for associated structural and chromosomal abnormalities. Thus differences in our results from those of earlier reports are not unexpected. In a retrospective review of the intrapartum FHR tracings of 16 fetuses with major cardiovascular anomalies, Garite et al.5 found a 12.5% incidence of abnormal FHR baseline, a 31% incidence of absent FHR reactivity, and a 37.5% incidence of either persistent late decelerations or severe variable decelerations. This group of patients had a heterogenous mix of cardiac defects, many with abnormal karyotypes and other associated abnormalities.

Moodie et al.6 briefly outlined the pregnancy outcome of 11 newborns with hypoplastic left heart syndrome diagnosed after decompensation in the neonatal period. Eight of the 11 had vaginal deliveries, and three

underwent elective cesarean section. Meconium staining of the amniotic fluid was present in 2 (18%). Apgar scores at 1 and 5 minutes were >7 in nine of the 11 infants; the scores of the other two newborns were not reported. No mention is made in their report of anesthesia for labor and delivery, oxytocin use, intrapartum monitoring, FHR patterns, or umbilical cord blood pH measurements. This series is relatively homogenous in that all of the neonates had hypoplastic left heart syndrome, but all cases were diagnosed in the newborn period, and the focus of the report is from a viewpoint of pediatric cardiology with a paucity of information about the antepartum and intrapartum courses.

The antepartum management of a patient with a fetus with hypoplastic left heart syndrome should include a consideration of abortion if the diagnosis is made before the legal gestational limit for pregnancy termination. If abortion is chosen, the delivered fetus should have a full autopsy and chromosomal analysis, as any association of hypoplastic left heart syndrome with a karyotypic abnormality or syndrome will significantly alter the risk and counseling for subsequent pregnancies. For those with a later diagnosis or a strong desire to continue the pregnancy, obstetric managment should be guided by the results of fetal karyotype analysis and a targeted ultrasonographic survey of fetal anatomy; a policy of nonintervention on fetal behalf seems justified in cases with a chromosomal abnormality or other major structural malformations. Additionally, serial ultrasonographic evaluations in the third trimester seeking evidence of heart failure are warranted, because fetal hydrops may not manifest early in pregnancy and can significantly alter the outlook for survival.

Antenatal transport to a center providing cardiac surgical services has been reported to result in an improvement in the preoperative condition of newborns with hypoplastic left heart syndrome, with decreased incidences of metabolic acidosis and preoperative cardiac arrest.24 If surgical correction of the cardiac defect is anticipated, delivery in a tertiary care center providing pediatric cardiac surgical services should be arranged. If this is not possible and delivery is to occur in a location remote from the site of the planned repair, consultation with both a neonatologist and a pediatric cardiologist should be obtained well before the time of delivery to ensure the availability of appropriate care immediately after birth and to arrange newborn transport.

The results of our series suggest that the intrapartum period is not a high-risk situation for the fetus with hypoplastic left heart syndrome who is a surgical candidate, free of genetic abnormalities, coexisting major structural malformations, and cardiac failure. Labor, both spontaneous and induced, was well tolerated in our patients with no increased occurrence of FHR abnormalities, fetal distress, meconium staining, acidosis, or neonatal depression, compared with established rates for fetuses without cardiac abnormalities.7 Thus it seems that no special intrapartum precautions or monitoring are necessary. FHR assessment with either external cardiotocography or a scalp electrode is appropriate, with further evaluation of fetal status (scalp stimulation or blood sampling) being performed for standard indications.25 Elective abdominal delivery is not indicated for this group, and cesarean section should be reserved for customary obstetric conditions. Perinatal specialists should be involved in the antepartum management of these patients, and immediate neonatal care is crucial. Although delivery should take place in a tertiary care center, specialized high-risk care does not seem to be necessary for labor and delivery.

Fetal movement during labor

Uma M. Reddy, MD, Lisa L. Paine, CNM, DrPH, Carolyn L. Gegor, CNM, MS, Mary Jo Johnson, MD, and Timothy R.B. Johnson, MD

Baltimore, Maryland, and Providence, Rhode Island

The prognostic significance of antepartum fetal movement is well known; therefore it may be a variable in intrapartum fetal well-being. We report the simultaneous observation of fetal movement with fetal heart rate and uterine contractions by processed Doppler actograph signals during spontaneous labor of 22 normal women with normal fetal outcome. The mean percent incidence of fetal movement during labor was 17.3%. The percentage occurring during uterine contractions was 65.9%. Of all uterine contractions, 89.8% were associated with fetal movement. The proportion of time the fetus spent moving during uterine contractions (21.4%) was higher than between uterine contractions (12.9%). Uterine contractions associated with fetal movement were significantly longer than those not associated with fetal movement (p < 0.0001). Mean percent incidence of fetal movement did not differ significantly between latent and active-phase labor. This study demonstrates a clear relationship between fetal movement and uterine contractions in labor. (AM J OBSTET GYNECOL 1991;165:1073-6.)

Key words: Fetal movement in labor, Doppler actograph, fetal well-being

The presence of fetal heart rate (FHR) accelerations associated with fetal movement is the basis for antepartum nonstress testing, and the presence of coexisting fetal movement during the third trimester is indicative of fetal well-being.1,2 Animal studies have demonstrated the cessation of fetal body movements as an initial response to hypoxia.3 Therefore the absence of fetal activity may be a marker for hypoxia during labor in the human fetus. The few studies that have observed fetal movement during labor have done so with ultrasonography for only a small proportion of the entire course of labor. 4-10 In spite of their limitations, these studies suggest both the presence of fetal movement during labor and a significant correlation of fetal movement with uterine contractions. The purpose of this observational study was to quantitate fetal movement during the entire course of the normal labor process with a Doppler transducer capable of simultaneous detection of fetal movement and FHR, coupled with standard measurements of uterine contractions.

Material and methods

Twenty-two low-risk pregnant women with singleton fetuses with vertex presentation who were seen in spontaneous labor at the Johns Hopkins Hospital between

Presented at the Eleventh Annual Meeting of the Society of Perinatal Obstetricians, San Francisco, California, January 28—February 2,

Reprint requests: Timothy R. B. Johnson, MD, Director, Maternal-Fetal Medicine, The Johns Hopkins University, Houck 228, 600 N. Wolfe St., Baltimore, MD 21205. 6/6/30947 May and July 1990 were eligible for study. Maternal ages ranged from 15 to 31 years, with gestational ages between 36 and 42 weeks. All had essentially benign prenatal courses: One had sickle cell trait, none were illicit drug users (negative toxicology screens), the majority took no medications during pregnancy (four took short courses of antibiotics, two required terbutaline because of preterm contractions), and they were generally nonsmokers (two women smoked five or fewer cigarettes per day). All had adequate weight gain during pregnancy (between 21 and 55 pounds). The study group comprised 12 black and 10 white women.

After these women were determined to be in labor (more than three uterine contractions per 10 minutes or rupture of membranes), informed consent for participation was obtained. All received epidural anesthetic between 2 and 9.5 cm cervical dilation. Eight required oxytocin augmentation. In eight women membranes ruptured spontaneously, whereas the remaining 14 had membranes ruptured artificially.

All 22 fetuses had normal outcomes with 1-minute Apgar scores ranging from 6 to 9, 5-minute Apgar scores ranging from 8 to 10, and an average umbilical artery pH of 7.29 (one pH was <7.2). Twenty were delivered vaginally and two were delivered by cesarean section (one because of prolonged first stage labor, one because of prolonged second-stage labor with failure of the fetus to descend). The average birth weight was 3379 gm, with a range from 2600 to 4060 gm.

A Toitu MT-322 fetal monitor was used to obtain information on FHR, fetal movement, and uterine contractions during labor. FHR signals were processed in the usual manner with autocorrelation techniques. Fetal movement was measured by a Doppler signal of ≥8 Hz

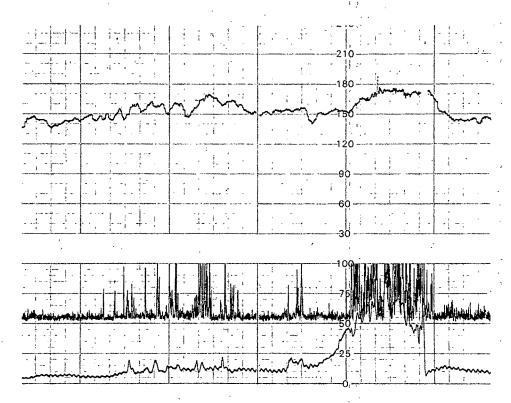

Fig. 1. Fetal monitor tracing showing three channels: top, FHR pattern; middle, Doppler actograph; bottom, uterine contractions. Note simultaneous occurrence of activity with uterine contraction and heart rate acceleration. Paper speed 3 cm/min.

introduced into a 20 to 80 Hz band-pass filter.¹¹ Previous work has related amplitude of recording to type of movement, with peaks >30 arbitrary units corresponding to fetal movement.^{11, 12} Uterine contractions were simultaneously recorded by the same monitor by external tocography or an intrauterine pressure catheter.

Once fetal surveillance with the Doppler actograph was started, the principal investigator (U.R.) supervised the fetal monitor tracing. Continuous tracings were obtained throughout labor, excluding time periods of interference because of maternal movement, vaginal examinations, epidural catheter insertion, and misplaced Doppler or tocography devices.

For study purposes fetal movement recorded at >30 units was used for evaluation (Fig. 1). Fetal movement was then grouped into epochs (period of movement lasting ≥2 seconds) for easier evaluation. The end of an epoch occurred when there was no fetal movement for >4 seconds. The duration of each epoch was considered in 2- to 4-second intervals (e.g., an epoch lasting >6 and <10 seconds would be rounded off to 8 seconds; an epoch >42 and ≤46 seconds would be 44 seconds). A single movement, <2 seconds in duration (likely an isolated limb activity) was counted as 1 second of movement. Therefore the duration of fetal movement was the summation of the duration of the epochs plus the duration of the isolated limb movements.

Fetal movement was further subdivided as not associated with uterine contractions and occurring between 10 seconds before the start of a uterine contraction and 10 seconds after the end of a uterine contraction. Uterine contractions were defined as an increase in uterine tone with a peak of >40 mm Hg and lasting a minimum of 40 seconds. Uterine contractions were divided as not accompanied by fetal movement and accompanied by fetal movement.

Finally, the labor process was divided into a latent phase (0 to 4 cm cervical dilatation) and an active phase (>4 cm dilatation). Individual Friedman curves were plotted to determine the probable time at which 4 cm had been reached.

The SYSTAT statistical package was used to perform paired *t* tests on the sample data. The incidences of the following were compared: fetal movement with and without uterine contractions, uterine contractions with and without fetal movement, and percent fetal movement in the latent phase and the active phase of labor.

Results

A total of 6885 minutes (114 hours) of monitor tracing during labor on 22 healthy fetuses was recorded. After exclusion of poor observation time associated with maternal movement, vaginal examinations, epidural insertion, and misplaced Doppler and tocography devices, 6052 minutes (100 hours) were evaluated. The

average duration of fetal movement constituted 17.8% of the recording period (range, 2.1% to 47.5%; SD, 11.4%).

The total durations of fetal movement without and with uterine contractions were 34.1% and 65.9%, respectively (p < 0.001). The percentage of fetal movement occurring during uterine contractions was significantly higher (Table I). The proportion of time the fetus spent moving during uterine contractions was significantly higher than between uterine contractions, 21.4% and 12.9%, respectively (p < 0.001).

A total of 1689 uterine contractions were recorded, occupying 3140 minutes, or 51.9%, of the recording period. Fetal movement accompanied 89.9% of the contractions, and 10.2% of the contractions were not accompanied by fetal movement (p < 0.001). The mean durations of uterine contractions without and with fetal movement were 65.8 and 117.0 seconds, respectively (p < 0.001). Therefore uterine contractions accompanied by fetal movement were significantly longer than those not accompanied by fetal movement.

In nine women the mean percentage incidence of fetal movement (the percentage of observation time during which the fetus was moving) in latent-phase and active-phase labor was compared. There was no decrease in the mean percent incidence of fetal movement as labor progressed.

Comment

Study findings concur with previous studies demonstrating fetal movement during labor. This study is unique in that fetal movement was conveniently monitored throughout the labor process concurrently with uterine contractions and FHR with the Doppler actograph. Previous studies have established the importance of antepartum fetal movement. Sadovsky and Yaffe¹³ showed that pronounced decreases in movement, culminating in the cessation of fetal movement, occurred in the terminal stages of fetal death in utero. Roberts et al.14 found that the incidence of fetal movement during the third trimester was 18%. Carmichael et al.15 found that before spontaneous labor at term there is a normal decrease in the incidence of fetal breathing movements but no similar change in the incidence of gross fetal body movements. Therefore the presence of gross fetal body movements is a more consistent index of fetal health before spontaneous labor

Boylan and Lewis¹⁶ observed a reduction, although not a statistically significant one, in the fetal movement index (percentage of observed time during fetal trunk movement) from the antepartum period to labor. Richardson et al.6 observed that the intermittent patterns of increased body movement and heart rate variability continued throughout the first stage of labor in spite of the decrease in fetal breathing activity during latent-

Table I. Percent fetal movement time in labor

Labor (mean)	17.3
Between uterine contractions	12.9
During uterine contractions	21.4

and active-phase labor. However, they found a decrease in fetal body movements, possibly related to the progress of labor. Similar findings were reported by Yarkoni and Hobbins,5 who demonstrated that the mean incidence of fetal movement in labor was 19.5% and that there was a linear decrease in percent incidence of fetal movement as cervical dilatation increased. This study found a mean percentage incidence of fetal movement similar to that of Richardson et al.6 and Yarkoni and Hobbins,5 indicating fetal movement to be a stable parameter at the onset of and throughout the labor process. Although observed only in a limited number of women, we noted no decrease in the percentage incidence of fetal movement as cervical dilation progressed. However, further study is required.

Similar to Sadovsky et al.8 and Zimmer et al.,4 we found a close relationship between uterine contractions and fetal movement. We determined an incidence of fetal movement without and with uterine contractions, of 31.8% and 66.2%, respectively, similar to the study of Zimmer et al. However, we found a significantly greater number of uterine contractions associated with fetal movement (89.8% of all uterine contractions). This is probably because of the greater sensitivity of the Doppler actograph apparatus for detecting isolated limb movements and the large number of uterine contractions that were evaluated. However, the effect of epidural anesthesia and oxytocin may have influenced these results, and further study is required on their effects.

Few studies have examined the implications of intrapartum fetal movement monitoring. Wittmann et al.7 concluded that absence of any fetal activity for more than 45 of the 60 minutes of observation during labor is significantly correlated with an abnormal FHR throughout the course of labor. During labor a healthy fetus has short episodes of respiratory movements and reacts to contractions with bursts of movement that are associated with an increase in the FHR. Decreased total activity may indicate a fetus at risk. Chr et al.17 found that fetal reactivity-not only antepartum but in the first stage of labor-is a reliable indicator of fetal wellbeing. They concluded that a nonreactive FHR pattern (lack of accelerations within 20 minutes of admission to the hospital for labor) during first-stage labor should arouse suspicion of intrauterine fetal compromise.

The Doppler actograph in conjunction with traditional FHR and uterine contraction recording is a convenient method for intrapartum fetal surveillance. This study demonstrates the presence of movement of healthy fetuses throughout labor and a clear relationship between fetal movement and uterine contractions. Ultimately, the Doppler actograph will allow us to evaluate fetal behavioral states during labor and determine the clinical implications of fetal movement during labor.

Editors' note

The AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY introduces a new format for abstracts accompanying regular articles, society articles, and Current Investigation articles. Authors submitting these manuscripts to the JOURNAL should provide an abstract of no more than 150 words structured according to the following headings: Objective(s), Study Design, Results, and Conclusion(s). Exceptions to this requirement include Clinical Opinion, Current Development, case reports, and brief communications articles. Abstracts for these articles will continue to follow the standard abstract format. Please consult the Information for Authors for details.

Oligohydramnios: Antepartum fetal urine production and intrapartum fetal distress

Lynn J. Groome, PhD, MD, John Owen, MD, Cherry L. Neely, RT, RDMS, and John C. Hauth, MD

Birmingham, Alabama

Animal and human studies suggest that fetal oliguria is a normal physiologic response to hypoxemia. To assess the clinical significance of this observation, we studied (before their admission) 51 fetuses of women whose pregnancies were complicated by oligohydramnios at ≥38 weeks' gestation. We found that the mean hourly fetal urine production decreased significantly in relation to the severity of subsequent intrapartum fetal compromise. The mean antepartum rate was 95 ml/hr in the 21 fetuses with a normal intrapartum heart rate pattern; this fell to 59 ml/hr in the 18 fetuses who had an abnormal intrapartum heart rate pattern but who responded to intrauterine resuscitation. The rate was 33 ml/hr in the 12 fetuses who were delivered by cesarean section as a result of fetal distress. These findings suggest that oligohydramnios associated with fetal oliguria may be used to identify those fetuses who have less intrinsic or uteroplacental reserve than do those of women with oligohydramnios who have a higher rate of fetal urine production. (Am J Obstet Gynecol 1991;165:1077-80.)

Key words: Oligohydramnios, fetal urination, fetal distress

The relationship between decreased amniotic fluid volume and adverse perinatal outcome¹⁻⁵ has led to the assessment of amniotic fluid volume as an integral part of antenatal fetal surveillance programs.⁵⁻⁷ Although a semiquantitative estimate of amniotic fluid volume is simple and rapid, there is currently no universally accepted definition of oligohydramnios. In 1981 Manning et al.¹ diagnosed oligohydramnios when the largest pocket of amniotic fluid was ≤1 cm in its greatest dimension. Chamberlain et al.³ later suggested that this criterion should be changed to ≤2 cm. Subsequently, a number of other semiquantitative methods^{8, 9} were proposed in an effort to improve the predictive value of a reduction in amniotic fluid volume.

Not only is there disagreement about what constitutes a clinically significant reduction in the amount of amniotic fluid, but the multiple pathways by which amniotic fluid is produced and the ways in which amniotic fluid volume is maintained ¹⁰⁻¹² make it difficult to determine the causes of oligohydramnios in every case. If no abnormalities exist in the genitourinary tract, oligohydramnios is often the result of a hypoxemia-induced reduction in renal blood flow that impairs fetal urine production. ¹³ Observations of the newborn infant

support the premise that perinatal asphyxia, in which a decreased rate of urine production may be present, adversely affects renal function. ^{14, 15} Additional support for this concept was recently provided by Nicolaides et al., ¹⁶ who reported a significant correlation between low hourly fetal urine production rates and fetal hypoxemia. In addition, animal studies ^{17, 18} suggest that fetal oliguria may be a normal physiologic response to hypoxemia.

However, because of the many possible pathways for amniotic fluid production and removal, other factors that are unrelated to hypoxemia may be responsible for the observed decrease in amniotic fluid volume. Of the possible fluid exchange routes, only the rate of fetal urine production can be assessed in utero by noninvasive means. ¹⁹ Because a hypoxemia-mediated decrease in fetal urine output may be responsible for a significant number of cases of oligohydramnios, it is reasonable to postulate that the condition is a disorder of varying severity and that those cases that arise as a result of fetal hypoxemia may be identified by a decrease in the rate of fetal urine production.

This study was designed to assess perinatal outcome in terms of fetal urine production in patients with oligohydramnios at ≥38 weeks' gestation. If a decrease in fetal urine production before the onset of labor is a result of unrecognized chronic hypoxemia in patients with oligohydramnios, then the fetuses of these patients may have an increased risk of experiencing fetal distress during labor.

Material and methods

Approximately 200 obstetric ultrasonographic examinations are performed each week by four experi-

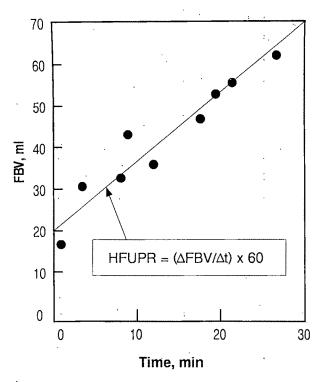

Fig. 1. Fetal bladder volume (FBV) in milliliters as a function of time (in minutes) for single fetus. Circles denote clinical measurements and solid line is least-squares best fit; slope of this line is rate of fetal urine production (HFUPR) (in milliliters per minute).

enced technicians in the Ultrasound Laboratory at the University of Alabama at Birmingham. A GE RT-3000 is used for all obstetric scans. In this study, which was approved by the institutional review board, diagnosis of oligohydramnios was based on the visual qualitative estimate of amniotic fluid volume, which was assessed by an experienced ultrasonography technician. When patients with oligohydramnios were identified, the semi-quantitative method originally described by Phelan et al.9 was performed and the amniotic fluid index measured was recorded in the computerized data base. This information was not made available for decisions regarding management of patients. Patients with qualitative oligohydramnios were recruited for this study only if the amniotic fluid index was also ≤8 cm. Exclusion criteria included estimated gestational age <38 weeks, an underlying maternal and/or obstetric complication, a nonvertex presentation, a multiple gestation, and any evidence of overt fetal distress at the time of evaluation.

Oligohydramnios was confirmed by one of the authors (C.L.N. or L.J.G.) before the rate of fetal urine production was measured. All measurements of the fetal bladder were made by either C.L.N. or L.J.G. The technique used to measure the hourly fetal urine production rates was similar to that described recently by Rabinowitz et al. 19 Longitudinal and transverse scans of

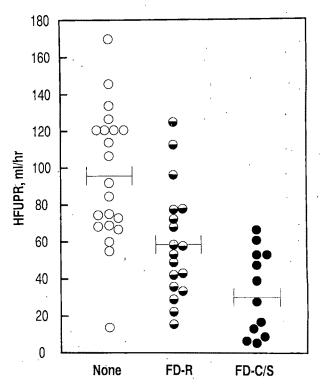

Fig. 2. Hourly fetal urine production rate (HFUPR) for three different outcomes: no fetal distress (open circles), fetal distress responsive to intrauterine resuscitation (half solid circles), and cesarean section because of fetal distress (solid circles).

the fetal bladder were performed at its greatest dimension, and the transverse, longitudinal, and anteroposterior diameters were recorded. The fetal bladder volume was calculated with the equation: Fetal bladder volume = 0.52 × Transverse diameter × Longitudinal diameter × Anteroposterior diameter. Fetal bladder measurements were taken after micturition and were performed at 3- to 5-minute intervals for a period of approximately 30 minutes. The time corresponding to each fetal bladder volume was taken to be the average value of the time recorded at the measurement of the longitudinal diameter and the time recorded at the measurement of the transverse diameter. To estimate the mean hourly fetal urine production rates, a graph of the fetal bladder volume versus time was prepared for each fetus, and the mean hourly fetal urine production rates was then determined from the slope of the line that best fit these data (Fig. 1).

At the University of Alabama at Birmingham, any patient with a term gestation is generally admitted for delivery when the diagnosis of oligohydramnios is made. The mean hourly fetal urine production rates for each study patient was computed in the clinic, usually several days after the patient had been delivered and without the clinic staff's knowing the delivery outcome. In no case was the hourly fetal urine production rate made available to the physicians managing these

patients. In addition, the managing physicians were unaware that the patients were part of an ongoing

Labor and delivery care is provided by the resident staff under the direct supervision of in-house faculty. Fetal distress was considered to be an abnormality of the heart rate pattern (usually persistent late decelerations or baseline bradycardia) that was sufficient to require initiation of fetal resuscitation or an immediate cesarean section. Intrauterine resuscitative efforts included the cessation of oxytocin, an intravenous infusion of crystalloid, placing the patient in a lateral recumbent position or changing the patient's position, and the administration of oxygen. All decisions to perform a cesarean section because of a persistent abnormality in the fetal heart rate pattern were made by the attending faculty.

Results

The study population of 51 gravid patients included 27 multiparous women; the group was predominantly nonwhite (69%). The mean age of the patients was 23 ± 5.7 years, and the mean gestational age at delivery was 41 ± 1.1 weeks (range, 38 to 43 weeks). The mean interval from hourly fetal urine production rate determination until delivery was 0.76 ± 0.95 days (range, 0 to 5 days). Only three of the 51 patients had thick meconium at the time of amniotomy. Cord arterial blood gas data were available on 44 patients. Nine fetuses were considered to have evidence of acidemia (pH < 7.2). Of these nine, four were considered to have a primary respiratory acidemia, and five had either a mixed or indeterminate acidemia.20 Two of these nine were considered to have had reassuring fetal heart tracings, two responded to intrauterine resuscitation, and the remaining five underwent a cesarean delivery because of fetal distress. All 51 neonates have a 5-minute Apgar score >7. According to the criteria of Brenner et al.,21 only one patient was delivered of an infant whose birth weight was <10th percentile, whereas seven were considered to be >90th percentile.

The study population was divided into three groups according to the presence and the nature of intrapartum fetal distress. The control group (n = 21) consisted of fetuses whose intrapartum heart rate pattern was normal. Fetuses who had persistent heart rate abnormalities in the first or second stage of labor but who responded to intrauterine resuscitation or were delivered vaginally formed the second group (n = 18). The third group (n = 12) consisted of patients who required cesarean delivery because of a persistent fetal heart rate abnormality. There was no difference in the mean gestational age among the three groups (p =0.39). The 12 infants who were delivered by cesarean section because of fetal distress had a mean hourly fetal urine production rates of 32 ml/hr, compared with 57

ml/hr for fetuses who responded to intrauterine resuscitation and with 95 ml/hr for fetuses who showed no evidence of distress (Fig. 2). Wilcoxon's rank-sum test indicated that that were statistically significant differences in the hourly fetal urine production rates between the group with no sign of fetal distress and the group who responded to intrauterine resuscitation (p = 0.002) and between the control group and those requiring a cesarean section because of fetal distress (p < 0.001).

Comment

The purpose of this prospective study was to determine whether the rate of fetal urine production is related to the intrapartum fetal heart rate pattern in women with oligohydramnios at term. We found that fetuses who were delivered by cesarean section because of fetal distress had significantly lower hourly fetal urine production rates when compared with fetuses who exhibited no sign of fetal distress during labor (32 vs 95 ml/hr, p < 0.001).

Animal studies suggest that fetal oliguria may be an important component of the fetal adaptive response to hypoxemia. A significant decrease in the rate of fetal urine production has been observed in fetal sheep after partial occlusion of the umbilical cord17 and during maternal hypoxia.18 At least two factors may be responsible for a reduction in fetal urine output in this setting. First, there is a redistribution of the combined ventricular output to maintain oxygen delivery to vital organs: Blood flow to the fetal brain, heart, and adrenal glands is either maintained or increased during hypoxemia, whereas blood flow to less vital organs, such as the kidney, is decreased.^{22, 23} This reduction in renal perfusion results in a decrease in the rate of urine production by the fetus.24 A second factor is an increase in the reabsorption of free water in the distal tubules.18 This effect is probably mediated by antidiuretic hormone,18 because fetal hypoxemia is known to be a potent stimulus for antidiuretic hormone release25 and because antidiuretic hormone infusion produces a decrease in fetal urine output.26

Clearly the effect of the diagnostic criteria used to establish the diagnosis of oligohydramnios must be considered. Our study population consisted of patients who were thought to have a decreased amniotic fluid volume as determined by a technician experienced in ultrasonography. Although an amniotic fluid index ≤5 cm has been suggested as being abnormally low in a postterm population,7 we arbitrarily chose an amniotic fluid index of ≤8 cm as a semiquantitative definition of oligohydramnios in this group of mostly term gestations. Trimmer et al.27 recently reported a decrease in the hourly fetal urine production rates in eight pregnancies at ≥42 weeks' gestation that were complicated by oligohydramnios, in comparison with similar measurements in 30 pregnancies at ≥42 weeks' gestation that had normal amniotic fluid volume. In that study oligohydramnios was diagnosed when the maximum vertical dimension of the largest amniotic fluid pocket measured ≤1 cm. In our study population seven pregnancies were ≥42 weeks' gestation at the time of evaluation; in this small group the mean hourly fetal urine production rates was 67 ml/hr, which is almost three times the rate reported by Trimmer. The reason for this discrepancy is not apparent at this time, although the criteria used to define oligohydramnios differed considerably between the two studies and both studies involved a relatively small number of patients with oligohydramnios at ≥42 weeks' gestation.

We conclude that measurements of the hourly fetal urine production rates may help to identify fetuses with clinically significant oligohydramnios. In our study population a useful definition of fetal oliguria appears to be an hourly fetal urine production rate ≤60 ml/hr. If the end point of a cesarean delivery because of fetal distress is considered, this cutoff has a sensitivity of 83% but a specificity of only 64%. Although these preliminary data are encouraging, larger prospective studies are required to confirm our results and to more fully delineate the predictive value and ultimate clinical use of this finding.

Antepartum fetal surveillance tests during sickle cell crisis

Akolisa Anyaegbunam, MD, Marie-Ignace Gauthier Morel, MD, and Irwin R. Merkatz, MD Bronx, New York

A study was conducted to evaluate the characteristics of antepartum fetal assessment tests for women with sickle cell disease during crisis. A total of 24 women with 39 episodes of crisis after 34 weeks of pregnancy were studied. All subjects were evaluated with nonstress tests, biophysical profile score, and uterine and umbilical artery systolic/diastolic ratios during and after sickle cell crisis. Results revealed that the incidence of nonreactive nonstress tests was significantly higher during crisis compared with the period after crisis (58.9% vs 10.3%, p < 0.05). The frequency of biophysical profile score <8 was significantly higher during crisis compared with after crisis (33.3% vs 7.7%, p < 0.05). All subjects had an increase in uterine systolic/diastolic ratio during crisis. The average uterine systolic/diastolic ratio was 3.92 (range, 2.16 to 4.24) during crisis and 2.54 (range, 1.98 to 3.23) after crisis (p < 0.05). In contrast, there was no significant change in the mean umbilical systolic/diastolic ratios during and after crisis (2.58 and 2.62, respectively). We conclude that, although sickle cell disease crisis is associated with a higher incidence of abnormal biophysical test results, in most patients these results will revert to normal after crisis. The increase in uterine vascular resistance without a concordant increase in umbilical vascular resistance suggests that the transient effects of sickling during crisis may not compromise umbilical blood flow. (AM J OBSTET GYNECOL 1991;165:1081-3.)

Key words: Sickle cell crisis, Doppler, nonstress test.

Sickle cell disease is characterized by a number of serious medical problems, including sickle cell crisis, acute chest syndrome, and multiple-organ abnormality.1-5 Painful vasoocclusive crisis is the most common cause of morbidity and the most frequent reason for short-term hospitalization.4 Pregnancy has been associated with an increase in the frequency of painful crises, especially in the last trimester and immediately postpartum. Although fetal surveillance tests such as the nonstress test (NST), contraction stress test, and Doppler studies have been used in the evaluation of pregnancies complicated by sickle cell disease, 5.6 the characteristics of these tests during sickle cell crisis have not been well described previously. The purpose of this investigation was to evaluate the characteristics of antepartum fetal assessment tests for a relatively large group of women with sickle cell disease during crisis.

Material and methods

In a prospective study design, 24 women with sickle cell crisis during the third trimester of pregnancy who attended the prenatal clinic at Albert Einstein College of Medicine between December 1988 and January 1991

From the Department of Obstetrics and Gynecology, Albert Einstein College of Medicine.

Presented at the Eleventh Annual Meeting of the Society of Perinatal Obstetricians, San Francisco, California, January 28—February 2, 1901

Reprint requests: Dr. Akolisa Anyaegbunam, Bronx Municipal Hospital Center, Department of Obstetrics and Gynecology, Room 709, Eastchester and Pelham Pkwy., Bronx, NY 10461. 6/6/30942

were studied. Diagnosis of acute painful crisis was made by sudden or insidious onset of intense pain involving the abdomen, chest, back, or extremities necessitating hospitalization. After careful evaluation patients were generally treated with hydration and analgesia. Subjects were evaluated with NSTs, biophysical profiles, and uterine and umbilical systolic/diastolic ratios on admission with sickle cell crisis and after the crisis.

The NSTs were performed with patients placed in the left lateral position. Either a model III (Corometrics) or a model 9020 (Hewlett-Packard) fetal monitor with an external tocodynamometer was used.

Fetal movements were documented by the mother using an event marker. A reactive NST was defined as two fetal heart rate accelerations associated with fetal movement in a 20-minute observation period.⁷

A tracing test that did not meet the reactive criteria in an 80-minute period was considered nonreactive.⁸ The criteria for the interpretation of the biophysical profile were those described by Manning et al.⁹ All components of the biophysical profile, including NST, fetal movements, fetal breathing movements, fetal tone, and amniotic fluid volume, were assessed, and a normal result received a score of 2. The maximum biophysical profile score is 10. For some analyses scores were classified as ≥8, <8, and <6.

The diagnostic evaluations to measure uterine and umbilical systolic/diastolic ratios for these women were performed with a continuous-wave Doppler instrument with a 4 MHz transducer. The technique for obtaining both the uterine and umbilical systolic/diastolic ratios has been previously described.⁶ The flow-velocity

Table I. Selected characteristics of study population (N = 24)

	Mean ± SL
Maternal age (yr)	27 ± 6
Nulliparity (%)	62.5
Hemoglobin (gm/dl)	7.9 ± 1.1
Gestational age during crisis (wk)	36.2 ± 2
sestational age during crisis (wk)	30.4

Table II. Distribution of biophysical profile scores during and after crisis

Biophysical profile score	During crisis (n = 39) (%)	After crisis (n = 39) (%)	p Value
≥8	66.3	82.3	
<8	33.3	7.7	< 0.05
<6	5.1	. 2.5	NS

Table III. Frequency of abnormalities in individual biophysical profile parameter during and after crisis

	During crisis $(n = 39)$ $(\%)$	After crisis (n = 39) (%)	p Value
Fetal movement	33.3	7.7	<0.05

NOTE: None of the subjects had decreased amniotic fluid volume. NS, Not significant.

waveforms were quantitated by the ratio of peaksystolic/end-diastolic flow velocity.10, 11

Statistical analyses were performed with χ^2 analysis for categoric data and paired t test for continuous data.

Results

There were 39 documented episodes of sickle cell crisis in the 24 subjects. Selected clinical characteristics of this study population, including maternal age, parity, hemoglobin level, and gestational age, are given in Table I.

The proportion of nonreactive NSTs was significantly higher during crisis compared with the period after crisis (58.9% vs 10.3%, p < 0.05).

The frequency of biophysical profile scores <8 was significantly higher during crisis as compared with after crisis (33.3 vs 7.7%, p < 0.05, Table II). The higher frequency of biophysical profile scores <6 during crisis

as compared with after crisis was not statistically significant.

Evaluations of individual parameters of the biophysical profile revealed that NST and fetal movement were the most frequent abnormalities and were significantly associated with crisis. The proportions for NST and fetal movement were 33.3% and 58.9%, respectively, during crisis compared with 7.7% and 10.3% after crisis (Table III).

All subjects had an increase in uterine systolic/diastolic ratio during crisis. The mean uterine systolic/diastolic ratio was 3.92 (range, 2.16 to 4.24) during crisis and 2.54 (range, 1.98 to 3.23) after crisis (p < 0.05). In contrast, there were no significant changes in the umbilical systolic/diastolic ratios during and after 38 of 39 crises in these women. One patient had abnormality of both uterine and umbilical systolic/diastolic ratios during and after crisis. This was associated with recurrent late decelerations and poor (<6) biophysical profile score. She was delivered by cesarean section of a male infant with Apgar scores of 3 and 6 at 1 and 5 minutes, respectively. The birth weight was 1990 gm at 36 weeks of gestation (<10th percentile for 36 weeks).

Comment

The ability to optimally manage the pregnant woman in sickle cell crisis requires appropriate interpretation of maternal and fetal parameters. The high proportion of nonreactive NSTs during crisis that reverted to normal and the significant difference in fetal activity tests during and after crisis suggest the need to assess all other available information. Interpretation of these findings is facilitated by the proposed mechanism of crisis and disparate results of uterine and umbilical systolic/diastolic ratio.

Vasoocclusive crises are probably due to accumulation of rigid, sickled red blood cells in areas of the microcirculation, causing precapillary and capillary obstruction.12 These events may result in formation of microthrombi and a further decrease in oxygen tension and worsening of the sickling process. The abnormal uterine systolic/diastolic ratio could be explained by the above phenomena, resulting in an increase in uterine vascular resistance. The absence of significant change in the umbilical systolic/diastolic ratio suggests that the events that started on the maternal side did not compromise the fetal circulation. In a previous study6 we showed that adverse neonatal outcomes in pregnancies complicated by sickle cell disease require both maternal and fetal-placental circulations to be compromised, which can be a time-dependent phenomenon. In the current series one patient with abnormally high uterine and umbilical systolic/diastolic ratios required intervention after crisis. This abnormality was associated

with recurrent late fetal heart decelerations. Cesarean section was performed, with delivery of a small-forgestational-age infant having low Apgar scores.

Most investigators agree that a reactive NST has a good negative predictive value13-15; however, concordance has not been demonstrated for women in sickle cell crisis. This study suggests that a nonreactive NST obtained during crisis does not necessarily correlate with increased perinatal morbidity and mortality in the absence of other abnormal findings.

As for the NST, the biophysical profile may be less predictive of outcome in the range of 6 to 8 during crisis, and the strength expected for its predictive potential for adverse outcome may be lessened in these high-risk pregnancies.

Further investigations on larger groups of women with sickle cell disease are needed to understand the mechanisms, assessment modalities, and natural history of crisis in these women. Given the rare incidence of pregnancy in this high-risk population, it is imperative to regionalize management centers and clinical data bases so that these unanswered questions may be resolved.

We conclude that, although sickle cell disease crisis is associated with a higher incidence of abnormal biophysical test results, in most patients these results will revert to normal after crisis. The increase in uterine vascular resistance without a concordant increase in umbilical vascular resistance suggests that the transient effects of sickling during crisis may not compromise. umbilical blood flow.

Maternal perception of decreased fetal movement as an indication for antepartum testing in a low-risk population

Janice E. Whitty, MD, David A. Garfinkel, MD, and Michael Y. Divon, MD Bronx, New York

Maternal perception of decreased fetal movement has traditionally been used as an indication for fetal testing in high-risk patients. Two hundred ninety-two low-risk patients who presented with a complaint of decreased fetal movement were studied to determine the incidence of adverse outcome and need for further testing. Initial testing included a nonstress test and ultrasonographic examination. Five (1.7%) of the study group had fetal death on initial examination and 4.4% of patients required immediate delivery because of abnormal maternal or fetal evaluation. An additional 5.8% had abnormal fetal heart rate tracings that necessitated follow-up. Fifty-two percent of patients with normal initial evaluations underwent additional testing. There were no significant differences between patients undergoing additional testing, patients having no additional testing, and a low-risk nontested group with regard to adverse outcome. Fetal surveillance is indicated in low-risk patients with decreased fetal movement. Additional testing of patients with a normal initial evaluation and no further complaint of decreased fetal movement may not be necessary. (AM J OBSTET GYNECOL 1991;165:1084-8.)

Key words: Decreased fetal movement, low-risk patient, antepartum testing, fetal outcome

Antepartum fetal deaths account for more than half of all perinatal mortality, and in one institution 70% of nonanomalous stillborn infants weighing > 1000 gm resulted from seemingly normal pregnancies.1 Any effort to detect fetal compromise and prevent antenatal mortality may be best served by routine antepartum fetal evaluation. Schifrin et al.2 demonstrated that antepartum fetal testing will predict fetal outcome more accurately than will antenatal risk assessment with an established scoring system. Routine antenatal evaluation of all pregnancies with use of ultrasonography and external fetal monitoring would clearly tax limited resources, but maternal assessment of fetal activity is a simple, inexpensive, and probably effective means of monitoring fetal condition. Sadovsky and Polishuk³ described the "movement alarm signal," a pronounced reduction or cessation of fetal movements or of their vigor for at least 12 hours while fetal heartbeats were still audible. Fetal outcome was improved if delivery was accomplished as soon as this movement alarm signal was observed. These findings have been corroborated by several other authors whose observations were made in patients with identifiable high-risk condi-

tions. 4-10 The clear advantage of maternal surveillance of fetal movement in high-risk patients has led many clinicians to have all their patients monitor fetal movement. The purpose of this study was to evaluate a low-risk patient population whose only complaint was decreased fetal movement for these parameters: (1) the incidence of abnormal fetal test results necessitating immediate intervention, (2) the percentage of patients with incidental abnormal ultrasonographic findings, and (3) the need for long-term follow-up of fetuses with a normal initial evaluation.

Material and method

The Maternal-Fetal Testing Center of the Weiler Hospital of the Albert Einstein College of Medicine serves antepartum patients referred by their private obstetricians. These patients are from a racially mixed, middle- to upper-middle-class socioeconomic background. All patients registered for delivery in our institution were instructed in writing to monitor fetal movement daily and to report any period of decreased fetal movement (fewer than four per hour for two consecutive hours) to their obstetrician. The evaluation of patients presenting with a complaint of decreased fetal movement consisted of confirmation of history of perceived decreased fetal movement by an obstetric nurse, a blood pressure measurement, a urine screen for glucose and protein, a nonstress test (NST), and an ultrasonographic evaluation. The ultrasonographic examination included fetal presentation, placental location and grade, evaluation of amniotic fluid volume, estimated gestational age, and fetal weight, as well as a

screen for fetal anomalies. An abnormal NST result was followed by biophysical profile scoring.11 Patients who had evidence of maternal or fetal compromise such as elevated blood pressure, late fetal heart rate decelerations, fetal heart rate bradycardia, biophysical profile score <6, or oligohydramnios (a pocket of amniotic fluid <2 cm × 2 cm or an amniotic fluid index value¹² <5 cm) were admitted to the labor floor for further evaluation or delivery. Patients with a nonreactive or equivocal NST, biophysical profile score ≥6, and adequate amniotic fluid were advised to have follow-up examinations as were patients with intrauterine growth retardation, macrosomia, and abnormal placentation or presentation. Additional testing of patients with a normal initial evaluation was at the discretion of the referring physician. The study group comprised all low-risk patients presenting with a complaint of decreased fetal movement during the study period. Six hundred twenty-three consecutive, low-risk, nontested patients who were delivered at the Weiler Hospital during the same period served as a control population. Perinatal morbidity was defined as cesarean section because of fetal distress (defined by either an abnormal fetal heart rate tracing in early labor or an abnormal, scalp pH, whenever possible), an Apgar score ≤6 at 5 minutes, thick meconium, birth weight ≤10th percentile for gestational age, neonatal intensive care unit admission for reasons unrelated to prematurity, or perinatal death. Statistical analysis was performed by means of the χ^2 test; a p value of <0.05 was considered significant.

Results

Of the 4727 patients evaluated in the Maternal-Fetal Testing Center between January 1985 and April 1990, 292 (6.2%) low-risk patients presented with a primary complaint of decreased fetal movement. These patients had no history of medical or obstetric problems and were well up to the time of presentation. The mean maternal age was 28 years (range, 14 to 42 years). Fifty percent of patients were nulliparous, and the neonatal birth weight (mean \pm SD) was 3550 \pm 431 gm. The patients ranged in gestational age from 26 to 42 weeks at the time of initial evaluation. Seventy-six patients (26%) were <36 weeks' gestational age and 17 (5.8%) were >41 weeks' gestational age. All patients underwent initial antepartum testing because of their perception of decreased fetal movement. Sixty-two (21%) patients had some abnormality on initial evaluation that required intervention or follow-up (Table I). Fetal death was diagnosed in 5 patients (1.7%) on initial evaluation. The gestational ages of the patients with fetal death ranged from 33 to 37 weeks; 3 patients were <37 weeks. None of these patients had underlying medical or obstetric problems, and none of the stillborn fetuses

Table I. Initial evaluation of low-risk patients with decreased fetal movements

	n	%
Fetal death on initial examination	5	1.7
Incidental ultrasonographic findings	27	9.2
Admission for immediate intervention	13	4.4
Abnormal fetal heart rate necessitating follow-up	17	5.8
Normal initial examination result	230	78.8

had congenital anomalies. None of the patients who had a live fetus on initial evaluation had fetal death during the subsequent period of observation. These incidental ultrasonographic findings were noted: intrauterine growth retardation, 8 (2.7%); macrosomia, 13 (4.5%); abnormal presentation, 5 (1.7%); placenta previa, 1 (0.3%). There were no fetal anomalies or multiple gestations noted in the study group.

A total of 13 (4.4%) patients were admitted for delivery because of abnormal fetal heart rate, biophysical profile score <6, oligohydramnios, or preeclampsia. Four had intrauterine growth retardation and late fetal heart rate decelerations, 6 had oligohydramnios, and three had severe preeclampsia. They ranged in gestational age from 35 to 41 weeks 5 days and were considered low risk by their private physicians. Five (38.5%) of these 13 patients were ≥41 weeks' gestational age, and these patients accounted for 71% of admissions with oligohydramnios. None of them had undergone testing before presentation with complaints of decreased fetal movement. The cesarean section rate of the patients admitted for delivery was 46%, and all cesarean sections were done because of fetal distress. One neonate was admitted to the neonatal intensive care unit after vaginal delivery. This patient was 35 weeks' gestational age with intrauterine growth retardation and a 40% placental infarction. Apgar scores were 8 and 9 at 1 and 5 minutes, respectively, and the birth weight was 1410 gm (<10th percentile for gestational age). This neonate did well and was eventually discharged home. All other patients admitted for delivery had 5-minute Apgar scores ≥8, and there were no other neonatal intensive care unit admissions.

An additional 17 (5.8%) patients who presented with decreased fetal movement had abnormal fetal heart rate tracings that necessitated follow-up examinations (such as nonreactive NSTs or variable decelerations). One patient in this group was admitted for observation. Gestational age in this group ranged from 29 to 41 weeks. The average number of follow-up visits was 4 (range, 1 to 20). Fourteen patients had vaginal deliv-

eries at term with appropriately grown fetuses. Labor was induced in one patient because of an ultrasonographic diagnosis of intrauterine growth retardation at 37 weeks' gestational age, which was subsequently confirmed by birth weight. Another patient in this group had a nonreactive NST at 31 weeks of gestation. She underwent a total of 10 follow-up examinations. Intrauterine growth retardation was diagnosed by ultrasound examination at 34 weeks of gestation, and at 40 weeks of gestation the fetus had a biophysical profile score of 4 and in addition preeclampsia was diagnosed. Labor was induced and the patient was delivered of a 2690 gm fetus (i.e., intrauterine growth retardation). One cesarean section was performed in this group because of preeclampsia in a term patient; this fetus was appropriately grown. All of the fetuses in this group had 5-minute Apgar scores ≥8 and there were no neonatal intensive care unit admissions.

All but two of the 66 patients who were <37 weeks' gestational age on initial evaluation were delivered at term (one was delivered at 33 weeks and the other, at 36 weeks). One patient had a cesarean section because of preeclampsia at 41 weeks; all 5-minute Apgar scores were ≥8, and there were no neonatal intensive care unit admissions.

Six hundred twenty-three consecutive, low-risk, nontested patients who were delivered at the Weiler Hospital during the same period served as a control population. The mean maternal age was 27 years (range, 15 to 43 years). Forty-three percent were nulliparous, the neonatal birth weight (mean \pm SD) was 3410 \pm 570 gm, and the mean gestational age at delivery was 38.6 weeks. Outcome characteristics of these patients are presented in Table II.

Fifty-two percent of patients with decreased fetal movement and a normal result of initial evaluation underwent additional testing. An average of two examinations per patient was performed with a range of I to 20. There were no significant differences in outcome between patients who underwent additional testing, patients having no additional testing, and the low-risk, nontested control group with regard to fetal distress in labor, thick meconium, low Apgar scores, or neonatal intensive care unit admissions (Table II).

Comment

Fetal movement is one of the first signs of fetal life. The mother first becomes aware of fetal movement (quickening) between the sixteenth and twentieth weeks of gestation. This quickening can assist in calculating gestational age, and when it is present for ≥25 weeks, one can be 90% certain that the fetus is beyond the 38th week of gestation.18 Daily fetal movement increases in vigor and frequency with maximum values detected between the 29th and 38th weeks of pregnancy.3 Two weeks before labor there is a slight decrease in the weekly average of fetal movement.3, 5, 8 The reason for this decrease remains unresolved. It has been suggested that the decrease in amniotic fluid volume coupled with the increased fetal size may explain the decreased movement. Normal fetal activity observed subjectively or objectively is an indication of fetal health, and the absence or diminution in fetal movement may indicate fetal death or impending fetal death.14

Fetal movement recording by the mother is a wellestablished method of antepartum fetal assessment. It is easily used by most patients, and maternal assessment of activity correlates well with values obtained with recording devices. 15, 16 It is inexpensive and noninvasive and is not significantly affected by educational level, obesity, gestational age, or smoking status.16 We have examined a group of low-risk patients who were monitoring fetal activity as an ongoing screening tool. Sixty-

^{*}When low-risk nontested patients are compared with patients with decreased fetal movements and normal initial evaluation.

two (21%) of the patients in the study group had abnormalities necessitating intervention or follow-up, demonstrating the usefulness of maternal assessment of fetal movement. Five (1.7%) patients presented with fetal death. This incidence is much lower than that reported by Leader et al.,8 who evaluated 39 high-risk patients with decreased fetal movements and reported a 38.5% incidence of stillbirth.

The patients in our study group who presented with fetal death on initial examination probably represent patients who suffered acute fetal distress as described by Sadovsky and Polishuk.3 One would probably not be able to salvage these fetuses with maternal evaluation of fetal movement. The fetuses that one might hope to rescue are those that are suffering unsuspected uteroplacental insufficiency with subsequent hypoxia, either long-standing or of gradual onset, as in the patient with intrauterine growth retardation and/or hypertensive disorders of pregnancy. The patients in our study group who required admission for delivery all fell into this category, exhibiting fetal heart rate decelerations, a biophysical profile score <6, oligohydramnios, postdate pregnancy, intrauterine growth retardation, and preeclampsia. Most of these patients had intrapartum fetal distress, a further indication of uteroplacental insufficiency. Fetal morbidity was an associated finding in 8 of the 13 patients who required admission immediately after the initial evaluation. Similarly Liston et al.1 reported "fetal compromise" in 63.6% of their high-risk patients presenting with decreased fetal movement. None of our patients who presented with live fetuses had fetal death during the period of observation. Grant et al.,17 in a large multicenter, multinational prospective study, suggest that there is at best minimal benefit from formalized maternal counting of fetal movement. They observed 17 antepartum fetal deaths in patients who presented with live fetuses but complained of decreased fetal movement. None of these patients were delivered emergently, and it is possible that misleading antepartum testing or suboptimal management contributed to the unhappy outcome in many of these cases.

Twenty-seven (9.2%) of the study patients had incidental abnormal ultrasonographic findings; the most common were macrosomia and intrauterine growth retardation. We did not find any fetal anomalies, but this is probably a result of the relatively small sample size and the fact that most of these private patients had an ultrasonographic examination at 18 to 20 weeks of gestation. All of these ultrasonographic findings were of clinical significance and afforded an opportunity for appropriate management.

Ahn et al.18 suggested that patients with decreased fetal movement, normal NST results, and normal amniotic fluid volume, with no other indication for testing, do not require follow-up testing. Our results concur. Two hundred thirty (78.8%) of the study patients had a normal initial result at evaluation. When patients with a normal initial evaluation and no additional testing were compared with those who had additional testing, there was no significant difference in perinatal outcome. In addition, there was no evidence of increased fetal compromise in the patients who presented with a complaint of decreased fetal movement and had a normal initial evaluation as compared with a low-risk nontested population (Table II). These conclusions are limited, however, by the relatively small sample size, which may result in a type II error, and also because there is no practical way of ascertaining how many patients in the low-risk population actually monitor fetal movement as instructed.

Therefore we conclude that it is prudent to evaluate low-risk patients who present with a complaint of decreased fetal movement. In addition, ultrasonographic examination of these patients may provide useful information. Because of the inability to assess the reliability of individual perception of decreased fetal movement, it seems reasonable that patients who continue to complain of decreased fetal movement undergo follow-up examinations. Further testing of low-risk patients with normal initial results of evaluation and no further complaint of decreased fetal movement probably is not indicated.

Correlation of amniotic fluid index and nonstress test in patients with preterm premature rupture of membranes

James A. Harding, MD, David M. Jackson, MD, David F. Lewis, MD, Carol A. Major, MD, Michael P. Nageotte, MD, and Tamerou Asrat, MD

Orange and Long Beach, California

The amniotic fluid index and the nonstress test are commonly used in the expectant management of preterm premature rupture of membranes. This study was designed to investigate the interrelationship of the nonstress test and the amniotic fluid index during the preterm premature rupture of membranes latency period. Fifty patients with preterm premature rupture of membranes for >48 hours were prospectively followed with daily 1-hour nonstress tests and blinded, daily amniotic fluid index examinations (totaling 422 evaluations). The overall average daily amniotic fluid index was statistically lower in the earlier gestations and nulliparous patients but was not influenced by the fetal position or nonlaboring uterine activity. An increased incidence of variable decelerations and nonreactive nonstress tests was associated with a significantly lower overall average daily amniotic fluid index, but these differences were beyond the standard precision of the amniotic fluid index examination. The daily nonstress test appears to identify clinically significant lower fluid volumes during the latency period and should remain the mainstay in the management of preterm premature rupture of membranes. (AM J OBSTET GYNECOL 1991;165:1088-94.)

Key words: Amniotic fluid index, premature rupture of membranes, nonstress test, expectant management of premature rupture of membranes, fetal evaluation

Premature rupture of the membranes occurs in approximately 10% of pregnancies¹ with a high incidence in the preterm (<37 weeks) gestation. Preterm premature rupture of membranes has been associated with a high degree of maternal and perinatal morbidity and mortality.¹⁴ Over the past 10 to 15 years, conservative, expectant management to achieve prolongation of gestation has been one commonly practiced approach

careful assessn complications. Amniotic flu

survival.^{5,8} The major risks associated with expectant management include chorioamnionitis, endometritis, maternal and fetal sepsis, stillbirth, cord prolapse, fetal distress, and fetal positional deformities.^{1-4, 9} Considerations in the management of the patient with preterm premature rupture of membranes should include a careful assessment for development of these potential

Amniotic fluid assessments in patients with preterm premature rupture of membranes have been advocated in delineating patients at increased risk for infection, shortened latency periods, and increased perinatal mortality. ¹⁰⁻¹³ Amniotic fluid assessments have also been helpful in estimating the potential response to tocolysis. ¹⁴ The nonstress test (NST) in preterm premature

Reprint requests: James A. Harding, MD, Department of Maternal-Fetal Medicine, University of California, Irvine Medical Center, 101 The City Dr., Orange, CA 92668. 6/6/31424 rupture of membranes has been used to identify labor, variable decelerations,9 intrauterine infection, and possible neonatal sepsis.11, 15 Decreased amniotic fluid volumes have been correlated with an increased incidence of cord compressions and fetal heart rate decelerations.9, 16, 17

The interrelation between the amniotic fluid volume and NST findings during the latency period of patients with preterm premature rupture of membranes has not been previously reported. We investigated daily changes in the amniotic fluid volume and correlated NST findings with these changes.

Material and methods

Patients with preterm premature rupture of membranes were prospectively collected from June 1989 until July 1990 from the patient population at Women's Hospital, Long Beach Memorial Medical Center, Long Beach, California. The inclusion criteria were singleton pregnancies with estimated gestational ages ranging between 23 and 34 weeks at the time of premature rupture of membranes. In addition, study patients had to have a minimum of 48 hours of latency, to allow for two consecutive daily amniotic fluid index measurements. Patients with chronic hypertension, systemic lupus erythematosus, diabetes, genital bleeding, multiple gestation, evidence of intrauterine growth retardation, or major fetal congenital anomalies were excluded.

Rupture of membranes was confirmed on admission by sterile speculum examinations with pooled fluid, ferning, and Nitrazine paper determinations. All patients were initially evaluated for evidence of labor, chorioamnionitis, and fetal distress, and, if appropriate, an assessment of fetal lung maturity was obtained. Estimated gestational ages were obtained by best obstetric dates, confirmed by an admission ultrasonographic examination, and stratified for each evaluation. Continuous fetal monitoring was performed for the first 24 hours after premature rupture of membranes and extended if any evidence of active labor or fetal compromise occurred. If undelivered, the patients were placed in the antepartum suite for in-hospital bed rest with vital sign evaluations every 4 hours and minimal activity limited to bathroom privileges. Daily 60-minute NSTs were performed on all patients and evaluated for reactivity, fetal decelerations, persistent fetal tachycardia, and uterine activity.

Amniotic fluid assessments were performed at similar times daily, by means of the amniotic fluid index with the four-quadrant technique described by Phelan et al.18 Daily amniotic fluid index results were blinded to the managing physicians. Patients were delivered for evidence of chorioamnionitis, fetal distress, spontaneous labor, or fetal lung maturity. The relative change in the amniotic fluid index from one day to the next was calculated by the difference between the previous day's index and the present day's index, divided by the previous day's index and then multiplied by 100. The overall average daily amniotic fluid index and relative daily change were the two primary outcome variables assessed in this study. These two outcome variables were then correlated to parity, gestational age, fetal position, uterine activity, fetal heart rate reactivity, and the presence of variable decelerations.

The NST evaluations for clinical management were performed daily and evaluated by the attending physician. For purposes of this report, all NSTs were reviewed without knowledge of the amniotic fluid index by a single interpreter. Fetal heart reactivity was defined as two or more fetal heart rate accelerations of ≥15 beats/min in amplitude and ≥15 seconds' duration during a 20-minute period. A variable deceleration was defined as a 30 beats/min decrease below the baseline heart rate for ≥15 seconds. Uterine activity was assessed during the 1-hour segment of the NST and was defined as the number of uterine contractions not associated with active labor identified during that hour.

Interobserver error was obtained by two observers comparing blinded amniotic fluid index examination within 1 hour of each other. Intraobserver error was calculated by the same observer repeating the amniotic fluid index examination within 1 hour of the previous examination.

Statistical analysis was performed incorporating χ^2 with Yates' correction, Fisher's exact test, and linear regression. All tests were against a two-sided alternative hypothesis, and a p < 0.05 was considered statistically significant. Results are reported in mean values ± 1 SD in the tables and the text.

Results

A total of 50 patients were enrolled in the study, and 422 individual examinations were performed. The average number of evaluations per patient was 10.3 (range 2 to 38). The study group analysis revealed a mean maternal age of 28.6 ± 4.3 years; 15 (30%) were nulliparous. The average gestational age at the time of preterm premature rupture of membranes was 29.7 ± 2.7 weeks (range 23.9 to 35.1 weeks) with a delivery age average of 30.7 ± 2.6 weeks (range 24.3 to 36.0 weeks). The overall average amniotic fluid index was 5.9 ± 2.1 cm (range 1.3 to 16.0 cm), and the average daily variation was $7.1\% \pm 45.1\%$ per day (range -74.0% to 205.0% per day).

Fig. 1 represents the scattergram comparing the daily amniotic fluid index evaluation with the gestational age at the time of the examination with the mean amniotic fluid index ± 2 SD delineated. The daily amniotic fluid index increases statistically with increasing gestational age, as seen in Table I, using linear regression analysis.

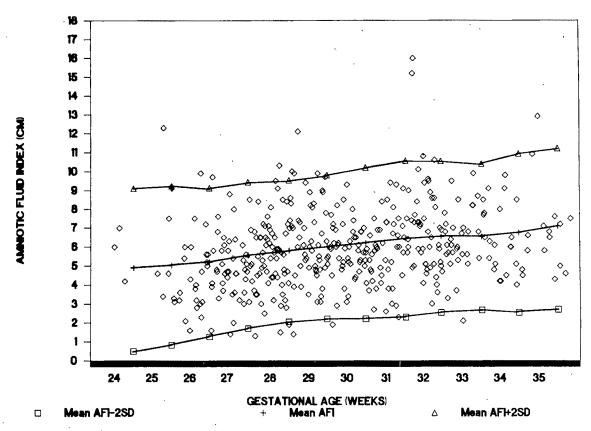

Fig. 1. Amniotic fluid index (AFI) in centimeters recorded in patients with premature rupture of membranes relative to gestational age at measurement in weeks. Mean anniotic fluid index and ± 2 SD curves are displayed.

Table I. Overall daily amniotic fluid index and variability in patient with preterm premature rupture of membranes in relation to gestational age, demonstrating statistically significant linear relationship (r = 0.27)

Gestational age (wk)	No. of evaluations	Daily amniotic fluid index (cm, mean ± 1 SD)	Change in amniotic fluid index (%/day, mean ± 1 SD)
23-24	4	5.5 ± 1.1	27.6 ± 53.1
25-26	47	4.9 ± 2.1	13.8 ± 65.5

35-36	12	7.1 ± 2.3	6.5 ± 28.2
p Value		< 0.005	NS

In comparison though, the rate of change in amniotic fluid index from one day to the next, also depicted in Table I, does not vary statistically as the gestational age increases.

Table II outlines the overall average amniotic fluid index and its day-to-day change in relation to parity, fetal position, and uterine activity. The amniotic fluid index was statistically lower in the nulliparous patient but was not significantly affected by fetal position or

uterine activity. The day-to-day variation was not significantly altered by parity, position, or uterine activity (Table II).

Nulliparous patients also had higher rates of variable decelerations compared with multiparous patients (40.0% vs 27.6%, respectively; p < 0.02), which appears to be unrelated to gestational age (29.8 \pm 2.7 vs 29.9 \pm 2.5 weeks, respectively; p not significant).

Table III reviews the incidence of variable deceler-

Table II. Overall daily amniotic fluid index and variability in patient with preterm premature rupture of membranes in relation to parity, fetal position, and number of uterine contractions per hour (uterine contraction statistical analysis by linear regression with respective r values documented)

Parameter	No. of evaluations	Daily amniotic fluid . index (cm, mean ± 1 SD)	Change in amniotic fluid index (%/day, mean ± 1 SD)
Parity

p Value	_	NS (r = 0.07)	NS (r = 0.08)

ations identified on the NST with a correlated amniotic fluid index measurement. The incidence of variable decelerations in the extremely low examination (0 to 1.9 cm) was 50% in comparison with an incidence of 0% in an amniotic fluid index \geq 10 cm (p < 0.01) by linear regression analysis.

Table IV reviews the relationship of the amniotic fluid index and its day-to-day changes with the corresponding alterations in the NST observations. Nonreactive NSTs were associated with a statistically lower amniotic fluid index than were reactive NSTs $(4.6 \pm 2.2 \text{ vs } 6.0 \pm 2.0 \text{ cm}, \text{ respectively; } p < 0.001).$ The variance of the day-to-day changes was high, ranging from 43.5% to 60.5% per day. Variable decelerations were associated with a statistically lower amniotic fluid index $(5.3 \pm 1.7 \text{ cm})$ versus no decelerations $(6.2 \pm 2.2 \text{ cm}), p < 0.001$. Gestational age was statistically lower in the patient evaluations associated with variable decelerations, nonreactive NSTs, and lower daily amniotic fluid index. The variance again was high in the day-to-day change in amniotic fluid index in association with the presence of variable decelerations, so no statistical correlation could be identified.

Tables V and VI tabulate further the changes in the NST outcome variables from one day to the next and lists the corresponding amniotic fluid index values. Table V indicates that the development of variable decelerations is associated with an overall lower amniotic fluid index, although the variance is high in the dayto-day change (38.8% to 43.7% per day) leading to statistical insignificance. Gestational age appeared to have no significant association with the development of variable decelerations nor with the changes in reactivity

Table III. Overall daily amniotic fluid index in patient with preterm premature rupture of membranes and corresponding relationship to presence of variable decelerations

4-5.9	160	36.8
6-9.9	185	25.4
≥10	12	0.0
p Value	_	< 0.01

 $\chi^2 = 13.04$, degrees of freedom = 4.

as seen in Tables V and VI, respectively. Table VI reveals a statistically lower amniotic fluid index found in the development of a nonreactive NST, although the change from the previous day is not statistically significant. The daily amniotic fluid index is lower in the nonreactive NST, as noted in Table IV, and is seen in Table VI as well, although the change from a nonreactive to a reactive NST does not have a statistically greater amniotic fluid index.

A total of 13 patients were randomly selected for development of the interobserver and intraobserver error for the amniotic fluid index examination. Intraobserver error was found to be 1.8 ± 1.6 cm or a relative variation of $45.7\% \pm 60.8\%$ (r = 0.64), with a mean time difference between examinations of 25.6 ± 22.2 minutes. The interobserver error was 1.7 ± 1.3 cm or a relative variation of $31.3\% \pm 18.9\%$ (r = 0.65), with

a mean time between the two examinations of 10.5 ± 6.9 minutes.

Comment

Amniotic fluid regulation in the patient with intact membranes is closely governed and remains fairly static on a day-to-day basis. ¹⁹ Amniotic fluid volumes, when measured with the amniotic fluid index, vary considerably on a day-to-day basis (7.1% \pm 45.1% per day) during the latency period in the patient with preterm premature rupture of membranes. Percent changes on

a daily basis indicate the fluid may decrease by as much as 75% and increase by up to 200% from one day to the next. The daily change in amniotic fluid index is of such magnitude that no individual variable seems to have a statistically significant effect on this change.

The amniotic fluid index variation with gestational age in patients with intact membranes has been well defined.^{18, 20} The amniotic fluid index has a gradual increase in value with advancing gestational age until approximately 24 to 26 weeks, at which point it levels

off until 34 weeks and then begins to decline. In the patient with preterm premature rupture of membranes, in contrast, it progressively increases with advancing gestational age, even past 32 weeks in our study population. The mean daily amniotic fluid index in these patients is <1st percentile by the standard curves generated for intact membranes.20 Nonreactive NST and presence of variable decelerations are noted in the lower gestational ages. It is uncertain if the gestational age alone accounts for these findings or whether they are caused by the lower amniotic fluid index values. One should conclude, though, that in the earlier gestations the higher the risk for variable decelerations, nonreactive NSTs and lower amniotic fluid index values, and therefore the higher risk for possible fetal compromise.

Uterine activity and fetal position surprisingly had little overall effect on the amniotic fluid index in the patient with preterm premature rupture of membranes in the nonlaboring state. The data suggest an overall loss of fluid from the previous day, when there were more than 10 contractions in the hour identified (-6.4% per day), but this was not statistically significant because of the broad variance. The uterine activity noted on the NSTs was generally asymptomatic and of little magnitude compared with that in the laboring patient.

The development of variable decelerations was noted with a lower overall amniotic fluid index, which correlates well with the work by Gabbe et al.,16 indicating an increase in variables when the amniotic fluid was removed from the chronic fetal rhesus monkey preparations. Patients with preterm premature rupture of membranes have a higher incidence of variable decelerations in labor and a subsequent higher incidence of fetal distress, possibly related to the decrease in amniotic fluid volume.9 At the same gestational age, nulliparous patients maintain statistically significant lower amniotic fluid indexes than multiparous patients. The explanation for this is uncertain, but with the lower amniotic fluid volumes the nulliparous patient tends to have a higher incidence of variable decelerations. The presence of nonreactivity in the NST is also correlated with a statistically lower amniotic fluid index (6.0 cm in the reactive NST vs 4.6 cm in the nonreactive NST). The development of nonreactivity or significant variable decelerations correlates with possible fetal compromise and infection.9, 11, 15

The major difficulty in using the amniotic fluid index measurement to identify the potentially compromised fetus is the innate precision error of the test. For example, the difference between the amniotic fluid indexes associated with the development of variable decelerations or nonreactivity is 0.9 cm and 1.2 cm, respectively. The interobserver error was 1.7 ± 1.3 cm in our population and is reported to be 0.97 cm²⁰ to 2.0 cm in intact membranes.21 The interobserver errors are statistically greater than the amniotic fluid index differences correlated with development of abnormal NST findings, indicating that the decrease in the amniotic fluid index may not be measured by the actual examination but may be suggested by the findings on the NST. Therefore, by measuring the amniotic fluid index only, a significant change in amniotic fluid index may not be appreciated because of the lack of precision of the test in the patient with preterm premature rupture of membranes.

In conclusion, the amniotic fluid index varies widely on a day-to-day basis in the latency period after preterm premature rupture of membranes. No one specific identifiable factor affects its day-to-day alteration. The overall index is lower in the nulliparous patient and in the earlier gestation. A lower amniotic fluid index is associated with an increased incidence of development of variable decelerations and nonreactivity in the NST. The average differences in the index associated with the development of these factors is beyond the precision of the examination. The NST evaluation in the prolonged latency period after preterm premature rupture of membranes provides better potential insight into the clinically reduced amniotic fluid volumes than the measured amniotic fluid index in the patient. The value remaining in amniotic fluid index assessment in the patient with preterm premature rupture of membranes may be in the initial examination where the amniotic fluid volume appears to be predictive of infection, duration of latency period, and response to tocolytic therapy. 10-12, 14

Variable decelerations in reactive nonstress tests with decreased amniotic fluid index predict fetal compromise

Iffath A. Hoskins, MD, Faith J. Frieden, MD, and Bruce K. Young, MD New York, New York

A total of 3158 patients at ≥34 weeks' gestation undergoing nonstress tests and amniotic fluid index determinations were divided into six groups according to the amniotic fluid index and the nature of the decelerations. Fetuses with antepartum decelerations had statistically significantly increased incidences of intrapartum decelerations and operative deliveries because of intrapartum "distress," regardless of the amniotic fluid index. They also had significantly increased rates of neonatal acidosis and low Apgar scores when there were "severe" decelerations and an amniotic fluid index <5 in the antepartum period. Thus spontaneous decelerations in reactive nonstress tests with an amniotic fluid index <5 may predict fetal compromise. (AM J OBSTET GYNECOL 1991;165:1094-8.)

Key words: Antepartum decelerations, oligohydramnios, fetal compromise

The reliability of antepartum fetal surveillance techniques to determine fetal well-being continues to be debated. There are conflicting reports in the literature

From the Department of Obstetrics and Gynecology, New York University Medical Center.

Presented at the Eleventh Annual Meeting of the Society of Perinatal Obstetricians, San Francisco, California, January 28-February 2,

6/6/30907

regarding the association of variable decelerations during nonstress tests (NSTs) and fetal compromise. 1-6 Sarno et al.7 have suggested that the amniotic fluid index is a useful adjunct to antepartum surveillance. They found that an amniotic fluid index ≤ 5 in the early intrapartum period was a risk factor for abnormal intrapartum fetal heart rate patterns.

The current study was conducted to assess the intrapartum and neonatal implications of variable decelerations occurring during reactive NSTs in patients with antepartum oligohydramnios.

Table I. Frequency of intrapartum decelerations

,		var	partum iable rations	Intrapar deceler

Material and methods

The study population consisted of patients with singleton, nonanomalous pregnancies ≥34 gestational weeks with intact membranes undergoing NSTs, amniotic fluid index assessment, and subsequent delivery at our institution from July 1987 to July 1990. Patients had weekly NSTs while lying in the lateral or semirecumbent position. The indications included diabetes, hypertension, suspected growth abnormalities, preeclampsia, underlying medical conditions, and previous poor obstetric history. Excluded were studies from 274 (7.9%) patients that showed uniform late decelerations, more than six contractions per hour, decelerations exceeding 1 minute's duration, absence of reactivity after 2 hours, or results that were uninterpretable because of technical reasons.

Reactive studies were defined by the presence of at least two 15-beat accelerations of at least 15 seconds' duration during a 20-minute period. For the purposes of this study, the decelerations were classified as mild or severe. Mild spontaneous variable decelerations were those lasting ≤ 15 seconds with a decline ≤ 20 beats/min below baseline. Severe spontaneous variable decelerations were those lasting >15 seconds with a decline >20beats/min below baseline.

Amniotic fluid index estimates were made with the four-quadrant technique previously described.8,9 A linear-array, real-time B scan with electronic calipers was used with the patients in the supine position. Landmarks for the four quadrants of the maternal abdomen included the umbilicus, which divides it into upper and lower halves, and the linea nigra, which divides it into right and left halves. The linear transducer was placed along the mother's longitudinal axis and held parallel to the floor for all measurements. The maximum vertical diameter of the largest fluid pocket was measured

in centimeters in each quadrant. Brief appearances of cord or an extremity were ignored, but aggregation of either one resulting in exclusion of fluid was excluded. The measurements obtained from each quadrant were summed to form the amniotic fluid index. An amniotic fluid index >5.0 was considered to reflect adequate fluid.8

When more than one type of deceleration appeared on the NST, the patients were grouped according to the most severe NST variable. These were matched to the lowest amniotic fluid index noted at any test performed within 10 days of delivery. Pregnancy outcome was assessed with respect to the following: (1) incidence and type of intrapartum decelerations, (2) fetal distress that required operative delivery (forceps or cesarean section), (3) Apgar scores <7 at 5 minutes, (4) neonatal acidosis (pH <7.20), (5) occurrence of terminal meconium, and (6) incidence of nuchal cords.

Fetal distress was defined as fetal bradycardia or fetal acidosis occurring at any time while the woman was in labor. At no time were the findings of the antepartum assessments (NST and amniotic fluid index) used to diagnose fetal distress. Fetal bradycardia was defined as a fetal heart rate <90 beats/min or a decline in rate of 40 beats/min below the baseline, lasting for >3 minutes. Fetal acidosis was defined as a scalp pH <7.20.

Sensitivity, specificity, and predictive values for fetal distress necessitating cesarean delivery were calculated for each variable. Statistical analysis was carried out with Fisher's exact test or χ^2 analysis, and significance was considered as p < 0.05.

Results

There were 3158 patients in the study who underwent NST and amniotic fluid index determination. The mean \pm SD for maternal age was 25.0 \pm 4.3 years

 $[\]uparrow p < 0.001$.

(range, 16 to 38 years). The estimated gestational age (mean \pm SD) was 36.3 \pm 2.0 weeks (range, 34 to 43 weeks). The medical and high-risk conditions were found to be equally distributed and not significantly different among the groups. There were 2132 patients in group 1, where the NST was reactive and the amniotic fluid index was >5. In group 2 there were 382 patients who had reactive NSTs but an amniotic fluid index ≤5. The 181 patients with mild spontaneous variable decelerations on NST and an amniotic fluid index >5 made up group 3. Group 4 had 109 patients; they showed decelerations similar to those in group 3 but had an amniotic fluid index ≤5. The 236 women who had severe spontaneous variable decelerations on NST and an amniotic fluid index >5 made up group 5. There were 118 women in group 6, in whom the decelerations were similar to those in group 5 but the amniotic fluid index was ≤5.

There was a strong association between antepartum decelerations occurring in a repetitive pattern and the finding of similar repetitive decelerations during labor, regardless of amniotic fluid index (Table I). This association achieved statistical significance when either the NST variables were more pronounced or the amniotic fluid index was ≤5. The most frequent occurrence of this association was seen when patients had severe variable decelerations on NST and oligohydramnios (amniotic fluid index, ≤5). Table II describes the occurrence of operative delivery (forceps or cesarean section) for the patients in the study. Once again, patients in groups 4, 5, and 6 had much higher rates of operative delivery because of fetal distress. The most frequent association was in group 6, in which 88% (104/118) had operative delivery.

Neonatal outcomes of these patients are shown in Table III. The birth weight percentiles were equally distributed and were not significantly different in the

six groups. The women in group 6 had a statistically significantly increased incidence of neonatal acidosis (37/118, 31%) and low 5-minute Apgar scores (15/118, 13%). There was a 2% incidence of nuchal cords and a 7% incidence of terminal meconium in the patients in group 1 (i.e., reactive NST and amniotic fluid index >5). In groups 2 through 6 the ranges of incidence of these events were 2% to 5% and 9% to 13%. These findings were similar to those of other investigators. 6, 10, 11 and were not statistically significant.

The sensitivity, specificity, and predictive values of mild and severe variable decelerations on NST and amniotic fluid index ≤5 because of subsequent fetal distress necessitating operative delivery and because of subsequent neonatal acidosis are shown in Table IV.

Comment

The idea of an antepartum risk scoring test is an attractive one because it might help to identify the 10% to 20% of low-risk patients who subsequently have intrapartum complications. 12, 13 Such a risk scoring system may allow patients to be triaged into high-risk or lowrisk status. Once a patient is considered high risk, her physician can be alerted to an increased risk of fetal intolerance to labor.

Previous authors have evaluated other diagnostic modalities in an attempt to predict intrapartum and neonatal complications. Ingemarsson et al.14 found a 75% risk for fetal distress after a nonreactive NST and acoustic stimulation test. Sarno et al. 15 studied 109 patients during early labor and found that abnormal initial fetal heart rate tracings and low amniotic fluid index results had very low positive predictive values for subsequent fetal distress. Even though these authors did not define fetal distress per se, they did define an abnormal tracing as one with evidence of variable or late decelerations or bradycardia. Additionally, amniotic

Table IV. Sensitivity, specificity, and predictive values of mild and severe variable decelerations

	Fetal distress necessitating cesarean section					Neonatal acidosis		
	Sensitivity (%)	Specificity (%)	Positive predictive value (%)	Negative predictive value	Sensitivity (%)	Specificity (%)	Positive predictive value	Negative predictive value
"Mild" variable decelerations on NST and amniotic fluid index ≤5	71.5	83.3	23.3	97.9	17.6	86.4	13.2	93.7
"Severe" variable deceler- ations on NST and amniotic fluid index ≤5	84.5	87.2	43.6	91.2	43.8	84.7	18.1	89.9

fluid index results were analyzed in all patients, even though 47.7% had ruptured membranes at the time of entry in the study. On the other hand, in our study all patients had intact membranes at the time of the amniotic fluid index assessment.

The observation that spontaneous variable decelerations (both "mild" and "severe") are predictive of intrapartum variable decelerations has already been shown by others. However, amniotic fluid index assessment was incorporated into the evaluation process in an attempt to identify an additional factor, i.e., oligohydramnios causing cord compression, that may help to predict fetal intolerance to labor. In our patients the existence of oligohydramnios along with variable decelerations seemed to further increase the risks for adverse perinatal outcomes (emergency delivery and neonatal compromise).

The neonatal outcomes in our patients differed from those of Judge et al." who found no increase in neonatal acidosis or low Apgar scores in 693 patients with variable decelerations on NSTs. Some of their patients (12% to 20%) also had decreased amniotic fluid, but

the method and results of the fluid assessments are unavailable. On the other hand, we found a significantly increased incidence of acidotic (pH <7.20) and depressed (5-minute Apgar scores <7) neonates born to mothers who had antepartum severe variable decelerations and an amniotic fluid index \le 5.

The current study was an attempt to use antepartum decelerations and oligohydramnios as a type of screening test to identify subsequent adverse intrapartum and neonatal compromise; therefore we calculated predictive values for these parameters. The positive predictive values were <50% for predicting emergency cesarean sections and <20% for neonatal acidosis. Both parameters showed high specificity (>80%) for adverse outcomes. It seems that, even though these tests can provide information regarding the increased incidence of intrapartum fetal distress or neonatal acidosis and depression, the low positive predictive values suggest that planned cesarean section delivery would not be warranted.

In conclusion, this study suggests that antepartum variable decelerations, especially if associated with decreased amniotic fluid volume, are an ominous finding. They may be useful in predicting subsequent adverse intrapartum and neonatal outcomes.

Preterm premature rupture of membranes: Detection of infection

Periclis Roussis, MD, Richard L. Rosemond, MD, Cheryl Glass, RN, BSN, and Frank H. Boehm, MD

Nashville, Tennessee

This prospective study was designed to determine the value of a daily modified biophysical profile in detecting infection in patients with preterm premature rupture of the membranes who were managed expectantly. Ninety-nine patients received daily nonstress tests and biophysical profile scores. Results of the last predelivery study were related to subsequent development of amnionitis or fetal sepsis. Infection was present in 16 patients. When the biophysical profile score was 0/8, infection was uniformly present. When fetal breathing was absent (biophysical profile score, ≤4/8) and nonstress test was nonreactive, infection was present in 75% of cases (sensitivity, 75%; specificity, 95%). Because a nonreactive nonstress test could be secondary to prematurity instead of infection, these results were analyzed over time. Those who initially had a reactive nonstress test that subsequently became nonreactive were more likely to be infected. We conclude that a daily biophysical profile score and nonstress test can detect infection and propose delivery of patients with a biophysical profile score of 0/8 and nonreactive nonstress test. Patients with absent fetal breathing and a nonstress test that changes from reactive to nonreactive also should be considered for delivery. Absent fetal breathing with a reactive nonstress test or a consistently nonreactive nonstress test should have further testing to rule out infection. (AM J OBSTET GYNECOL 1991;165:1099-104.)

Key words: Preterm premature rupture of membranes, biophysical profile, chorioamnionitis, fetal sepsis

Preterm premature rupture of membranes, defined as rupture of the membranes before the onset of regular uterine contractions, occurs in approximately 10% of all pregnancies and is associated with significant perinatal mortality and morbidity, primarily from premature delivery, sepsis, and asphyxia. In the preterm gestation, expectant management may minimize the risk of prematurity; however, delay of delivery may increase mortality and morbidity from infection and asphyxia.

If accurate methods were available for early detection of chorioamnionitis or fetal sepsis, outcome in these pregnancies perhaps could be improved. In the past these methods included observation of maternal vital signs, hematologic studies, analysis of amniotic fluid, and electronic fetal monitoring. All of these methods have their own unique deficiencies, and none provide the clinician with an ideal test. Recently, analysis of fetal behavior has been used to evaluate patients with

the presence of infection has been observed.

The purpose of this prospective study was to determine the ability of a daily modified biophysical profile examination to detect chorioamnionitis or fetal sepsis in patients with preterm premature rupture of membranes who were managed expectantly.

Material and methods

Vanderbilt University Medical Center is a level III regional referral center, serving a catchment area of approximately 25,000 deliveries per year. The institution receives approximately 700 inpatient maternal transports per year. The majority of patients in this study were transferred to Vanderbilt from a nearby facility with the diagnosis of preterm premature rupture of membranes.

Inclusion criteria in this study included: (1) documented preterm premature rupture of membranes, (2) singleton pregnancy with no known fetal anomalies, (3) gestational age <37 weeks, and (4) absence of other medical or obstetric complications.

All patients with suspected preterm premature rupture of the membranes were admitted to the labor and delivery suite for evaluation. Rupture of membranes

Table I. Modified ultrasonographic biophysical profile score

Fetal movements

Score 4 for two episodes of gross fetal movements within 30 min (simultaneous limb and trunk movements count as single episode)

Score 2 for one such episode of fetal movements Score 0 for no gross movements within 30 min Fetal breathing

Score 4 for two episodes of regular rhythmic fetal breathing of >30 sec duration within 30 min Score 2 for one such episode of fetal breathing Score 0 for no breathing within 30 min

The scores for each category are added. The maximum score is 8. Abnormal is defined ≤4. Other variables assessed but not scored include amniotic fluid level, fetal tone, and placental grade.

was documented by vaginal speculum examination with visualized pooled fluid, ferning, and alkaline pH determination. Routine vital signs were obtained, and physical examination was performed. Electronic fetal heart rate and tocodynamometer monitoring was used to detect fetal distress, as well as to document uterine activity. After an observation period of 12 hours, patients without evidence of labor, fetal distress, or infection were transferred to the antepartum unit for expectant management.

A total of 99 patients were entered in the study. Gestational ages were determined by last menstrual period and the results of any first-trimester or early secondtrimester ultrasonographic examinations. A level III ultrasonographic examination also was done at the time of admission in all patients to confirm the estimated gestational age and to rule out anomalies. All patients remained hospitalized for the duration of the study and were managed conservatively with bed rest and bathroom privileges. Cervical cultures were obtained on admission and patients were treated with ampicillin (2 gm in 100 ml normal saline solution infused intravenously every 8 hours) until culture results returned negative. Patients with positive group B streptococcus cultures were treated with the same regimen for 7 days and recultured. Temperature was taken three times a day, and physical examination was performed daily. Bimanual pelvic examinations were avoided unless the patient was believed to be in active labor or a decision to induce labor had been made. A 60-minute nonstress test (NST) was performed in all patients daily until delivery. At our institution, a reactive NST is defined as two or more fetal heart rate accelerations of at least 15 beats/min in amplitude and at least 15 seconds' duration in any 10-minute period. A fetal heart rate tracing that did not meet these criteria was considered nonre-

A modified biophysical profile score was obtained

every morning after breakfast in all patients by means of a real-time ultrasonographic method equipped with a 3.5 MHz curvilinear-array transducer. The method used has been previously described and is reviewed here only briefly.7 Real-time scanning consisted of a 30minute observation period during which fetal breathing movements and fetal body movements were observed. Each of the two biophysical variables was scored as 0, 2, or 4, according to the criteria in Table I.7 The modified biophysical profile was repeated every 24 hours until delivery. An abnormal profile, defined as a score of ≤4/8, was repeated twice with at least a 1-hour interval to reduce the risk of a low score being assigned to a normal fetus that is exhibiting normal periodicity of activity. The biophysical profile was not repeated once the diagnosis of amnionitis or labor was made. Results of the biophysical profile were not used in management decisions for any of the patients.

Indications for delivery in this patient population included labor, clinical diagnosis of chorioamnionitis, persistent spontaneous variable decelerations (moderate to severe)8 on electronic fetal heart rate monitoring, or mature fetal lung indices of amniotic fluid obtained by amniocentesis (lecithin/sphingomyelin ratio ≥3.5, phosphatidylglycerol present) (unpublished data, Vanderbilt University Hospital reference laboratory). The diagnosis of clinical chorioamnionitis was made in the presence of two or more of the following criteria: maternal fever >37.8° C, maternal tachycardia (≥120 beats/min), fetal tachycardia (≥160 beats/min), uterine tenderness, foul-smelling amniotic fluid and maternal leukocytosis (white blood cell count ≥20,000/mm³ with a left shift).9 All patients with clinical chorioamnionitis were given parenteral antibiotics and labor was induced, if they were not in labor. Cesarean section was performed for the usual obstetric indications.

On admission of all infants to the neonatal intensive care unit, blood, urine, and cerebrospinal fluid cultures were obtained. Chest x-ray films were obtained when indicated. Prophylactic antibiotics were administered and discontinued only when cultures were negative. The diagnosis of infection was made if blood, urine, or cerebrospinal fluid cultures were positive or if chest x-ray findings were consistent with pneumonia. Once neonatal sepsis was diagnosed, antibiotics were continued for 7 to 10 days.

Data collected after delivery included 1- and 5-minute Apgar scores, birth weight, umbilical artery cord blood pH (only if 1-minute Apgar score ≤7), route of delivery, placental cultures and pathologic evaluation, and results of neonatal septic workup. The results of the last modified biophysical study and NST before delivery were compared with the outcome of pregnancy in regard to the development of infection (clinical chorioamnionitis or neonatal sepsis). The association of

each biophysical variable and combinations of variables with the outcome was determined. Comparisons were made by using a two-sample t test or Fisher's exact test where appropriate.

Results

We performed 894 examinations among the 99 patients. The mean number of examinations per patient was 9 (range, 1 to 34). The mean gestational age on admission was 30.3 weeks (range, 24 to 35), the mean gestational age at delivery was 31.5 weeks (range, 24 to 37), and the mean prolongation of pregnancy was 8.7 days (range, 1 to 34 days). Of the 99 patients, chorioamnionitis or neonatal sepsis developed in 16 (16.1%). Fourteen of the 16 patients were diagnosed with amnionitis and four were diagnosed with neonatal sepsis. Two patients had both chorioamnionitis and neonatal sepsis (see diagnosis column in Table II). All 14 cases with amnionitis were confirmed by placental histologic examination.10 In the two cases of neonatal sepsis without clinical chorioamnionitis the placental histologic examination revealed chorioamnionitis in only one case.

Table III illustrates the demographic characteristics of the patients according to infectious outcome. There were no differences among the two groups with respect to maternal age, parity, 5-minute Apgar score, cord pH, or mean prolongation of pregnancy. The infected group had significantly lower mean gestational age on admission and at delivery, a lower birth weight (p < 0.01), and a higher incidence of low 1-minute Apgar scores (p < 0.01). Of the 16 infected cases delivery was performed in nine because of diagnosed antepartum amnionitis, in five because of simultaneous onset of labor and amnionitis, and in two because of spontaneous onset of labor alone. Of the 83 noninfected cases delivery was performed in seven because of persistent spontaneous variable decelerations, in two because of persistent vaginal bleeding, in six for mature

Table IV. Biophysical variables or combinations of variables and infectious outcome

Prevalence = 0.16.

fetal lung indices, and in 68 because of spontaneous labor. The cesarean section rate for the total population was 26% (26/99). Surgical indications included malpresentation (14/26), fetal distress (5/26), repeat cesarean section (5/26), and prolapsed cord (2/26).

There were 20 positive cervical culture results, three in the infected group (19%) and 17 in the noninfected group (20%). The pathogens recovered in the infected group included group B streptococcus (n = 2) and Candida albicans (n = 1). In the noninfected group the pathogens included group B streptococcus (n = 9), Staphylococcus aureus (n = 3), C. albicans (n = 3), gonococcus (n = 1), and group A streptococcus (n = 1). There was no significant difference between groups as to type and duration of antibiotic use.

The relationship between biophysical variables and infectious outcome is illustrated in Table IV. In 68 instances where the biophysical profile was repeated because of an initial abnormal score earlier in the day, 27 remained abnormal and 41 normalized. With rare ex-

ceptions, when the biophysical profile score was 4/8, absent fetal breathing accounted for the low score. There were no patients with absent fetal movement only. The calculated sensitivity, specificity, and positive and negative predictive values of each variable are listed in Table V. Illustrated in Table II are the individual score components of each case that was positive for infection.

With one exception all patients with infection had absent fetal breathing; however, there were 12 patients with absent fetal breathing who did not have infection. When absent fetal breathing was combined with non-reactive NST, there were fewer false-positive results and the test accuracy improved to 92%. The absence of fetal movement was specific for the presence of infection (100%) but had a low sensitivity (25%). When both fetal movement and fetal breathing were absent, all patients were infected and three of four (75%) had fetal sepsis. These neonates all had positive blood cultures. The bacterial organisms isolated were group B

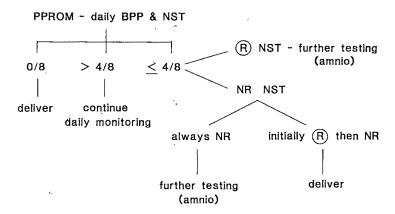

Fig. 1. Suggested protocol for management of patients with preterm premature rupture of membranes (PPROM). BPP, Biophysical profile; R, reactive; NR, nonreactive.

streptococcus (n = 2), Escherichia coli (n = 1), and enterococcus (n = 1).

There were two neonatal deaths and one stillbirth. Patient 8 (Table II) in the infected group was delivered of a 24-week fetus that died at 12 days of age of pulmonary hemorrhage. Patient 2 (Table II) in the infected group was delivered of a stillborn infant at 29 weeks after a cesarean section because of a prolapsed cord, and one patient in the noninfected group was delivered of a 241/2-week fetus that died at 2 months of age as a secondary consequence of renal failure. The perinatal mortality rate was 30:3 per 1000.

The NST résults were further analyzed over time, and these data appear in Table VI. Two of the nine patients who initially had reactive NSTs that then became nonreactive had infection and had absence of fetal breathing. Six of the remaining seven without infection had fetal breathing.

Comment

The expectant management of preterm premature rupture of membranes to gain more time for in utero fetal development may increase the risk of maternal or fetal infection. An accurate test for the early detection of chorioamnionitis or fetal infection is needed. Although many tests have been evaluated, no one test has proved to be ideal.8 The most promising tests have involved the use of ultrasonography to observe fetal biophysical activities with the hypothesis that behavior is different in the presence of infection than in its ab-

Other investigators have examined the relationship between the lack of fetal activity and infection and have found it to be accurate in predicting infectious outcome. 46 Problems and concerns with these studies, however, include the following: retrospective study design, test and outcome variables not independently assessed, use of a broad definition of infectious outcome, and an

Table VI. NST patterns compared with infectious outcome

	Infectious outcome

Always reactive $(n = 59)$	4	55		

^{*}Absent fetal breathing.

unusually high prevalence of disease.3 This study was designed to avoid these problems by use of a prospective study design in which test results were not used in patient management decisions and by a strict definition of infection as the presence of clinical amnionitis or neonatal sepsis:

The modified biophysical profile method as proposed by Shah et al.7 was chosen because it focuses on investigation of those fetal behaviors that are most likely to be affected by acute compromise of the fetal-maternal unit, namely, fetal movement and fetal breathing. Although the mechanism by which infection alters fetal behavior is not known, our results are consistent with the hypotheses that have been proposed. One such hypothesis is the gradual hypoxia concept,11 which states that in the presence of infection, as a progressive decrease in tissue oxygenation occurs, biophysical variables are lost in the reverse order to which they originally become present, i.e., reactivity of the NST is first to be lost followed by fetal breathing, then fetal movement, then fetal tone, and finally the occurrence of fetal death. Another hypothesis states that, in the presence of bacteria, phospholipase A2 is released, which increases prostaglandin production and may in turn de-

[†]Fetal breathing present in six.

crease fetal breathing. Another factor that may be released in the presence of infection is interleukin-1, which also may alter fetal behavior. It seems reasonable to postulate that as the severity of infection increases, a progressive loss of fetal activity occurs. This is supported by the study results that showed a 100% incidence of infection when the biophysical profile score was 0/8. We would thus recommend delivery for the expectantly managed patient with preterm premature rupture of membranes who has a persistent biophysical profile score of 0/8.

The presence of infection may alter fetal activity in a more subtle manner. Eleven of the 16 infected cases had absent fetal breathing but adequate fetal movement, yielding a biophysical profile score of 4/8. The positive predictive value of this parameter alone was relatively low (57.7%, Table V). To prevent the inappropriate intervention for a noncompromised preterm infant, it would be desirable to use a test with a higher positive predictive value. By combining absent fetal breathing with a nonreactive NST, the positive predictive value increased to 75%.

The accuracy of the NST is gestational age dependent, and it may be difficult to determine if a nonreactive NST is associated with immaturity of the fetal neural cardiac axis or early fetal compromise. The change in fetal behavior states over time may be helpful in evaluating the nonreactive NST in the premature fetus. In this study, if the NST was initially reactive and then became nonreactive, in conjunction with absent fetal breathing, two of the three patients had infection (66%). With loss of fetal heart rate reactivity with fetal breathing present, 6 of 7 (85.7%) did not have infection. Similarly, of those patients with absent fetal breathing and reactive NST, 8 of 11 (73%) did not have infection. However, a reactive NST does not always rule out infection, as 4 of 16 (25%) of the infected cases had a reactive NST.

It is concluded therefore that delivery should be considered for the patient with absent fetal breathing and an NST that has changed from reactive to nonreactive. If there is absent fetal breathing and the NST has always been nonreactive, further testing should be considered to rule out infection, i.e., amniocentesis. Those

patients with absent fetal breathing and reactive NSTs should be monitored closely for developing infection, and amniocentesis may be considered. A suggested protocol for management of preterm premature rupture of membranes is illustrated in Fig. 1.

· In conclusion, daily biophysical profiles and NSTs can detect the presence of infection in patients with preterm premature rupture of membranes. The suggested protocol in Fig. 1 is under investigation to determine if its use improves pregnancy outcome in these high-risk patients.

Correlation of amniotic fluid glucose concentration and intraamniotic infection in patients with preterm labor or premature rupture of membranes

Daniel W. Gauthier, MD, William J. Meyer, MD, and Andre Bieniarz, MD Chicago, Illinois

Amniotic fluid glucose concentration has previously been suggested as a rapid and sensitive test for diagnosing intraamniotic infection. In this study, 204 patients ≤34 weeks estimated gestational age with preterm labor or premature rupture of membranes underwent amniocentesis to detect subclinical intraamniotic infection. Amniotic fluid was cultured for aerobic and anaerobic bacteria, as well as for *Mycoplasma* species. Amniotic fluid glucose levels were significantly lower in patients with positive amniotic fluid cultures than in patients with negative cultures (median, 10 mg/dl; range, 1 to 62 mg/dl vs median, 31 mg/dl; range, 2 to 126 mg/dl, respectively; *p* < 0.001). In terms of predicting amniotic fluid culture results, an amniotic fluid glucose concentration of ≤16 mg/dl had a sensitivity of 79%, specificity of 94%, positive predictive value of 87%, and negative predictive value of 90%. The determination of amniotic fluid glucose concentration is useful in detecting subclinical intraamniotic infection in patients ≤34 weeks estimated gestational age with preterm labor or premature rupture of membranes. (AM J OBSTET GYNECOL 1991;165:1105-10.)

Key words: Amniotic fluid glucose, intraamniotic infection, prematurity

Subclinical intraamniotic infection has been associated with preterm labor and preterm premature rupture of membranes.1-5 The prompt diagnosis of subclinical intraamniotic infection is important in that it may prevent the maternal and neonatal morbidity associated with clinical chorioamnionitis. 6,7 Amniotic fluid cultures obtained by transabdominal amniocentesis have been used to diagnose early intraamniotic infection in patients with preterm labor or premature rupture of membranes.1-5 The culture results, however, may not be available for several days. Gram stain examination of the amniotic fluid is more rapid but has a low sensitivity, missing up to 55% of cases with intraamniotic infection.8 Other parameters, such as maternal fever, white blood cell count, C-reactive protein, or uterine irritability either occur too late or lack sufficient sensitivity and specificity to be of clinical benefit.9

Determination of amniotic fluid glucose concentration has been proposed as a rapid and sensitive test for the detection of intraamniotic infection in patients with preterm labor.¹⁰ The purpose of this prospective study was to evaluate the usefulness of amniotic fluid glucose concentration in predicting amniotic fluid culture results in patients with preterm labor or premature rupture of membranes.

Material and methods

The study population consisted of patients admitted to the University of Illinois Hospital with the diagnosis of preterm labor or premature rupture of membranes who had an estimated gestational age of ≤34 weeks and no overt clinical evidence of infection. Diabetic patients and patients receiving a β-agonist for tocolysis or betamethasone to enhance fetal lung maturity were included in the study. Patients on antibiotics were excluded from the study. The University of Illinois Hospital primarily serves indigent black and Hispanic patients. The study was approved by the institutional review board of the hospital.

Preterm labor was defined as regular uterine contractions associated with either documented cervical change or an initial cervical examination of ≥2 cm or 80% effacement. Premature rupture of membranes was documented by both a positive Nitrazine paper reaction and ferning test or by visualizing the leakage of amniotic fluid from the cervix.

After informed consent was obtained, transabdominal amniocentesis under ultrasonographic guidance was performed on each patient. The amniotic fluid was immediately placed, without exposure to air, in a transport vial suitable for anaerobic organisms (Port-A-cul, Becton Dickinson, Cockeysville, Md.) and brought to the microbiology laboratory. The amniotic fluid was cultured for aerobic and anaerobic bacteria and for

Mycoplasma hominis and Ureaplasma urealyticum. Gram stain for microorganisms was performed, and stained slides were examined by trained microbiology technologists. Intraamniotic infection was defined as a positive amniotic fluid culture.⁵ Clinical chorioamnionitis was defined according to the criteria of Gibbs et al.¹⁰

Amniocentesis is commonly performed at our institution to diagnose subclinical intraamniotic infection in patients \leq 34 weeks' estimated gestational age with preterm labor and premature rupture of membranes. During the study period, a positive Gram stain or a positive culture was an indication for delivery. These patients were started on parenteral antibiotics, and labor was induced or allowed to continue spontaneously. A culture that was positive for U. urealyticum alone was not considered an indication for delivery if there was no clinical evidence of maternal infection and if daily biophysical profiles were reassuring.

Amniotic fluid glucose concentrations were determined within 30 minutes of the amniocentesis. Analysis was performed by the glucose oxidase method with a Beckman glucose analyzer. The results of the amniotic fluid glucose concentrations were not used in patient management. Maternal serum glucose was determined by the same method at the time of amniocentesis.

All infants born prematurely underwent an evaluation for neonatal sepsis, consisting of blood and urine cultures. Cerebrospinal fluid cultures were done at the discretion of the neonatologist. Neonatal sepsis was de-

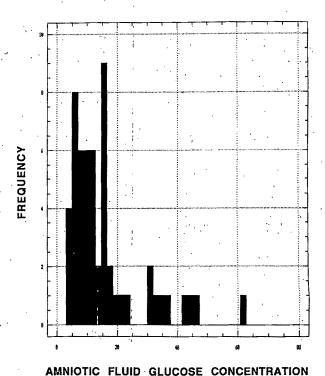

Fig. 2. Amniotic fluid glucose concentration in patients with positive amniotic fluid cultures.

fined as a positive blood, urine, or cerebrospinal fluid culture.

The Mann-Whitney test was used to compare amniotic fluid glucose concentration in patients with positive versus negative amniotic fluid cultures. A receiver operator characteristic curve analysis was performed to determine the relationship between the sensitivity and the false-positive rate for different values of amniotic fluid glucose in the detection of a positive culture. The sensitivity, specificity, and positive and negative predictive values for detecting positive amniotic fluid cultures were determined for amniotic fluid glucose and Gram stain. The sensitivities of amniotic fluid glucose and Gram stain in predicting positive culture results were compared by means of χ^2 analysis.

Results

Two hundred four patients were entered into the study. One hundred thirteen patients (55.4%) had preterm labor, and 91 (44.6%) had premature rupture of membranes. Amniotic fluid cultures were positive in 18 patients (16.0%) with preterm labor and 49 patients (53.8%) with premature rupture of membranes. Overall, the prevalence of positive amniotic fluid cultures in the study population was 32.8%.

Figs. 1 and 2 display amniotic fluid glucose concentrations in those patients with negative and positive cultures, respectively. Amniotic fluid glucose concentrations were significantly lower in patients with positive

amniotic cultures than in patients with negative cultures (median, 10 mg/dl; range, 1 to 62, vs median, 31 mg/dl; range, 2 to 126, respectively; p < 0.001). In analyzing the data from patients with preterm labor and premature rupture of membranes separately, median amniotic fluid glucose concentrations were similar with regard to amniotic fluid culture results. In patients with preterm labor and positive cultures, the median glucose concentration was 8.5 mg/dl, with a range of 2 to 18, versus a median glucose concentration of 31 mg/dl, with a range of 2 to 71, in patients with preterm labor and negative cultures (p < 0.001). In patients with premature rupture of membranes and positive cultures, the median glucose concentration was 11 mg/dl, with a range of 1 to 62, versus a median glucose concentration of 30 mg/dl, with a range of 2 to 126, in patients with premature rupture of membranes and negative cultures (p < 0.001). Maternal serum glucose concentration in patients with positive amniotic fluid cultures did not differ significantly from patients with negative cultures (89.4 mg/dl \pm 22.6 vs 87.8 mg/dl \pm 27.5, respectively).

The sensitivity, specificity, and positive and negative predictive values of amniotic fluid glucose ≤16 mg/dl and Gram stain are displayed in Table I. An amniotic fluid glucose concentration of ≤16 mg/dl was chosen as the cutoff value after analysis of the receiver operator characteristic curve. This was the level at which we felt the tradeoff between the sensitivity and the false-positive rate was most favorable. An amniotic fluid glucose concentration of ≤16 mg/dl was more sensitive than Gram stain in detecting positive amniotic fluid culture results (79.1% vs 29.9%, respectively; p < 0.001).

The eight cases in which amniotic fluid glucose concentration was ≤16 mg/dl and the amniotic fluid cultures were negative are summarized in Table II. Seven patients (87.5%) were delivered within 24 hours of the amniocentesis, with failure of tocolysis in five patients. The remaining two patients, both with a positive Gram stain, had intrapartum chorioamnionitis.

Table III summarizes the 14 cases in which the amniotic fluid glucose concentration was >16 mg/dl but the amniotic fluid cultures were positive. In this group there were four patients with amniotic fluid glucose levels <22 mg/dl. Two of these patients had a positive Gram stain and were delivered. The other two patients were delivered within 48 hours of amniocentesis without clinical evidence of maternal or neonatal infection. In the remaining 10 patients the amniotic fluid glucose concentration was ≥24 mg/dl and the amniotic fluid cultures were positive for *U. urealyticum* alone. All of these cases occurred in patients with premature rupture of membranes, in whom cervical cultures were also positive for U. urealyticum.

Clinical chorioamnionitis developed within 48 hours

Table I. Comparison of amniotic fluid glucose and Gram stain

	Amniotic fluid glucose level ≤16 mg/dl	Gram stain (%)
Sensitivity	79.1	29.9
Specificity	94.2	97.8
Positive predictive value	86.9	87.0
Negative predictive value	90.2	74.0

after the amniocentesis in 22 patients (10.7%). Amniotic fluid cultures were positive in 19 of these patients. The Gram stain was positive in two of the three patients with negative amniotic fluid cultures. Amniotic fluid glucose concentration was ≤16 mg/dl in 21 of the patients who subsequently developed clinical chorioamnionitis. The remaining patient had a glucose concentration of 17 mg/dl, a positive Gram stain, and a positive culture. There were no cases of documented neonatal sepsis in the study population.

Comment

The results of this study demonstrate that in patients ≤34 weeks' estimated gestational age with preterm labor or premature rupture of membranes, the amniotic fluid glucose concentration was significantly lower in those with positive amniotic fluid cultures than in those with negative cultures. This finding is consistent with the only other published report on amniotic fluid glucose concentration in intraamniotic infection by Romero et al.11 They performed amniocentesis on 168 consecutive patients with preterm labor and intact membranes. Amniotic fluid cultures were positive in 23 patients (13.6%). An amniotic fluid glucose value of <14 mg/dl had a sensitivity of 87%, a specificity of 92%, a positive predictive value of 63%, and a negative predictive value of 98% in the detection of a positive amniotic fluid culture. The higher positive predictive value in our study (87%) most likely is due to the higher prevalence of positive amniotic fluid cultures (32.8%).

In this study an amniotic fluid glucose concentration of ≤16 mg/dl predicted subclinical intraamniotic infection significantly better than Gram stain. The sensitivity of the Gram stain in our study is lower than what is generally reported in the literature. 1-5, 8, 9, 11 However, many of these studies did not culture for Mycoplasma species, which are not visible on Gram stain. Our results compare somewhat more favorably with a study by Romero et al.8 in which cultures for Mycoplasma species were performed. They reported a sensitivity of 44.8% for the Gram stain. The false-positive rate was higher with amniotic fluid glucose determinations than with Gram stain (5.8% vs 2.2%, respectively). If amniotic fluid glucose concentration is to be used clinically, the false-positive rate must be low to avoid the unnec-

essary delivery of a premature infant. In reviewing our eight cases of false-positive results, two cases (patients 1 and 2 in Table II) most likely represent instances of false-negative cultures. Both of these patients had a positive Gram stain, and clinical chorioamnionitis developed within 12 hours of the amniocentesis. Five of the six remaining patients had preterm labor that was unresponsive to tocolysis. These cases may represent instances of subclinical infection of the decidua, placenta, or membranes where the microorganisms had not yet reached the amniotic cavity. The remaining false-positive result occurred in a patient with a serum glucose concentration of 36 mg/dl.

Several factors have been associated with decreased amniotic fluid glucose levels, including intrauterine growth retardation, preeclampsia, low maternal glucose, and advanced gestational age.12-14 Weiss et al.12 demonstrated that amniotic fluid glucose concentration decreased as gestational age increased, with a mean of 26 mg/dl at 34 weeks, which decreased to 15 mg/dl at 40 to 42 weeks. The lower 10th percentiles were 15 and 9 mg/dl, respectively. These data, together with a less aggressive management of preterm labor and premature rupture of membranes in patients >34 weeks' estimated gestational age at our institution, led to the decision to exclude patients >34 weeks' estimated gestational age from our study. When intrauterine growth retardation, preeclampsia, or low maternal glucose is present, caution is necessary when the amniotic fluid glucose concentration is interpreted because false-positive results theoretically may occur more frequently in these situations.

The ideal management of preterm labor and premature rupture of membranes is controversial. The most widely accepted management in patients ≤34 weeks' estimated gestational age is to prolong the pregnancy, either with tocolytics in preterm labor or with conservative management in premature rupture of membranes. ^{15, 16} Thus false-negative results of amniotic fluid glucose concentration would be clinically less problematic because the usual management would not be affected. However, the mother and fetus may be at increased risk of infectious sequelae.

In this study there were 14 patients with false-negative results (Table III). In two patients the Gram stain was positive, and they were delivered. False-negative results occurred in 11 patients who had premature rupture of membranes and the culture was positive for *U. urealyticum* alone. Although the cause of a decreased amniotic fluid glucose level in subclinical intraamniotic infection is not known, this finding is not unexpected because *U. urealyticum* does not use glucose as a substrate. In these 11 patients there were no cases of clinical chorioamnionitis or neonatal sepsis. Therefore in patients with premature rupture of membranes an amniotic fluid culture that is positive for *U. urealyticum* alone may not be an indication to deliver a premature infant

Diabetes, tocolysis with a β -adrenergic receptor agonist, and betamethasone administration were associated with the highest amniotic fluid glucose concentrations in patients with negative amniotic fluid cultures. This included eight of the nine patients who had an amniotic fluid glucose level >60 mg/dl. This association

^{*}Lactobacillus, Peptostreptococcus magnus, a-hemolytic Streptococcus, Neisseria gonorrhoeae.

did not appear to be present in patients with positive amniotic fluid cultures. With the exception of patient 14 in Table III, who received terbutaline, all the diabetic patients and the patients who received a \beta-adrenergic receptor agonist or betamethasone with a positive amniotic fluid culture also had an amniotic fluid glucose level ≤16 mg/dl. However, until further research is done, caution should be exercised when amniotic fluid glucose concentration is used to assess for subclinical chorioamnionitis in patients with hyperglycemia.

In our study an amniotic fluid glucose concentration

of <13 mg/dl had a positive predictive value of 100% if patients 1 and 2 in Table II are considered to have false-negative amniotic fluid cultures. Similarly, a negative predictive value of 100% could be obtained for an amniotic fluid glucose concentration ≥22 mg/dl if patients without symptoms who had an amniotic fluid culture that was positive for U. urealyticum alone are excluded. In spite of this manipulation of the data, a gray zone of amniotic fluid concentrations exists between 13 and 21 mg/dl, which limits the clinical usefulness of the test. The serial amniotic fluid glucose

[†]Same amniotic fluid sample kept refrigerated.

[‡]No clinical evidence of maternal infection and no clinical or laboratory evidence of neonatal sepsis.

results obtained from patient 4 in Table III may indicate a possible method of improving the test. In this case a repeat amniotic fluid glucose concentration was done on the same sample, which was kept refrigerated, 16 hours after the initial determination. The amniotic fluid glucose concentration decreased from 21 to 4 mg/dl and the culture was ultimately positive for Klebsiella pneumoniae.

Amniotic fluid glucose concentration appears to be a rapid and sensitive test for detecting subclinical intraamniotic infection in pregnancies ≤34 weeks complicated by preterm labor or premature rupture of membranes. Further research is needed to determine the cause of the low amniotic fluid glucose levels found in association with intraamniotic infection and to develop modifications that improve the accuracy of the test in predicting amniotic fluid culture results.

Rate of recurrence of preterm premature rupture of membranes in consecutive pregnancies

T. Asrat, MD, D.F. Lewis, MD, T.J. Garite, MD, C.A. Major, MD, M.P. Nageotte, MD, C.V. Towers, MD, D.M. Montgomery, MD, and W.A. Dorchester, PhD

Orange and Long Beach, California

The reported incidence of preterm premature rupture of membranes ranges between 1% and 2% of all pregnancies. The rate of recurrence is poorly defined. The goal of this study was to establish the frequency of recurrence in a high-risk referral practice. Over a 5-year period we identified 121 patients with preterm premature rupture of membranes who had a minimum of two consecutive pregnancies under our care, resulting in a total of 255 pregnancies for analysis. Recurrent preterm premature rupture of membranes occurred in 39 of 121 patients, for a rate of 32.2% (95% confidence interval, 23.9 \pm 40.5). We were unable to demonstrate an association between the estimated gestational age at the time of rupture in the index pregnancy, latency period, interval between pregnancies, and the probability of repeat preterm premature rupture of membranes in the next pregnancy. We conclude that patients with preterm premature rupture of membranes should be counseled regarding the significant risk of recurrence and need to have close follow-up in their subsequent pregnancies. (AM J OBSTET GYNECOL 1991;165:1111-5.)

Key words: Preterm premature rupture of membranes, recurrence

Preterm premature rupture of membranes occurs in approximately 1% to 2% of all pregnancies.^{1, 2} The cause remains unknown in most cases, although many predisposing conditions have been proposed, including factors such as incompetent cervix, amnionitis, diethylstilbestrol exposure, uterine anomalies, multiple gestations, and trauma.

In many populations preterm premature rupture of membranes is the most commonly identified factor associated with preterm deliveries, occurring in >30% of all such births.^{3,4}

In counseling such patients we are currently unableto tell them the risk of recurrence of preterm premature rupture of membranes, yet in patients with less common causes of prematurity such as idiopathic preterm labor, abruptio placentae, fibroids, and polyhydramnios, we have accurate information from multiple studies.⁵⁻¹⁰ Therefore this study was pursued to close this important gap in our knowledge.

(days) Interval between pregnancies (mo)	28.5 ± 13.4

Data mean ± SD.

livered with the diagnosis of preterm premature rupture of membranes between 1983 and 1987. Preterm premature rupture of membranes was defined as rupture of membranes before 36 completed weeks. In all patients rupture of membranes was documented by sterile speculum examination with pooled fluid, ferning, and alkaline pH determination (Nitrazine paper). Best estimated gestational ages were derived from the last menstrual period and ultrasonographic examination on admission.

Patients with the diagnosis of incompetent cervix, uterine anomalies, diethylstilbestrol exposure, and multiple gestation and neonates with congenital anomalies were excluded from the data pool. During the study period 1050 patients with preterm premature rupture of membranes were identified; 121 met the inclusion criteria and had consecutive pregnancies under our care at Long Beach Memorial Medical Center, resulting in a total of 255 pregnancies for analysis.

Descriptive statistics are presented as the mean \pm 1 SD. Data were analyzed by means of χ^2 with Yates' correction, Fisher's exact test, and the Student t test. All comparisons were against a two-sided alternative

hypothesis, and a p value of <0.05 was considered statistically significant.

Results

Of the 121 patients evaluated, 110 underwent followup for one subsequent pregnancy and 11 patients had follow-up of two or more subsequent pregnancies, resulting in a total of 255 pregnancies. Preterm premature rupture of membranes recurred in 39 patients, for a rate of 32.2% (95% confidence interval, 23.9 to 40.5). As shown in Table I the average estimated gestational age at preterm premature rupture of membranes in the index pregnancy was \$1.4 ± 5.1 weeks. The average latency period was 5.5 ± 14.6 days, and the mean interval between pregnancies was 28.5 ± 13.4 months. Table II compares demographic and other characteristics between the group of patients without preterm premature rupture of membranes in their next pregnancy and those with recurrence. The differences observed did not achieve statistical significance. We then analyzed the effect of the length of the latency period in the index pregnancy on the probability of recurrence of preterm premature rupture of membranes in the next pregnancy; we were unable to demonstrate an association (Fig. 1). A similar analysis looking at the interval between pregnancies (Fig. 2), the gestational age at delivery in the index pregnancy (Fig. 3), and the gestational age at preterm premature rupture of membranes in the index pregnancy (Fig. 4) failed to show any significant associations with the risk of recurrence.

Comment

The issue of recurrence of preterm premature rupture of membranes in consecutive pregnancies has remained essentially unexplored. A 15-year review of the literature yielded only one such study performed by Naeye¹¹ in 1982. He reviewed the course of consecutive pregnancies of 5230 women who had been enrolled in the Collaborative Perinatal Project of the National In-

stitute of Neurological and Communicative Disorders and Stroke between 1959 and 1966. The total number of pregnancies analyzed was 10,460; however, the incidence of preterm premature rupture of membranes was not given. The rate of recurrence in patients with preterm premature rupture of membranes in their index pregnancies was 21%, as compared with only 4% when the index pregnancy went to term. A history of preterm delivery without rupture of membranes in the initial pregnancy was associated with a 10% risk of preterm premature rupture of membranes in the next pregnancy. The stated purpose of Naeye's study was to evaluate the factors that predispose to premature rupture of membranes. It was not specifically designed to address the question of recurrence. In addition, it is limited by the inherent errors in accurately assessing the estimated gestational age and the incidence of preterm premature rupture of membranes in such a wide collaborative study involving 12 centers and spanning 7 years.

In our study estimated gestational ages were calculated from the last menstrual period and were confirmed by an ultrasonographic examination, on admission in every case. By excluding patients with incompetent cervix, history of diethylstilbestrol exposure, uterine anomalies, and multiple gestations and fetuses with congenital anomalies, we tried to define a subgroup of patients with true idiopathic preterm premature rupture of membranes. Whereas we did not correlate the cervicovaginal microbiologic flora with the risk of recurrence, it is important to note that none of the 39 patients with recurrence had evidence of clinical amnionitis at the time of rupture of membranes in the second pregnancy. Surprisingly, we were unable to demonstrate an association between the estimated gestational age at the time of rupture in the index pregnancy and the probability of recurrence in the next pregnancy. Similarly, we were not able to show that patients with a longer latency period in the index preg-

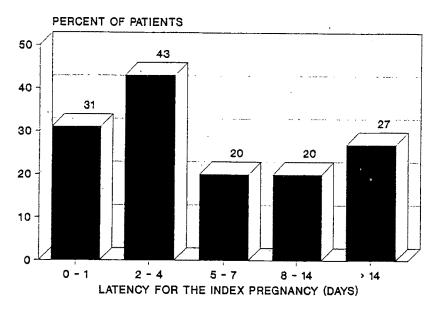

Fig. 1. Percent of patients with recurrent preterm premature rupture of membranes by latency period in index pregnancy.

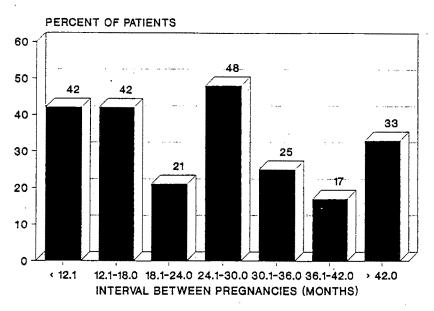

Fig. 2. Percent of patients with recurrent preterm premature rupture of membranes by interval between pregnancies.

nancy were less likely to have recurrent preterm premature rupture of membranes. The estimated gestational age at the time of preterm premature rupture of membranes in the index pregnancy of patients with recurrence was 30.9 ± 5.1 weeks, as compared with 33.0 ± 5.1 weeks at the time of the recurrence. Although the difference did not reach statistical significance (p=0.07), there was a strong trend suggesting that patients with recurrent preterm premature rup-

ture of membranes will have ruptured membranes at a later gestational age in the next pregnancy. The main limitation of this analysis is its low "capture" rate, having only 121 patients return to our care for their subsequent pregnancies. However, these patients returned to our hospital of their own accord and were not referred back by their private physicians. This, we believe, eliminates any selection bias that may have occurred. There is no apparent reason why patients who were

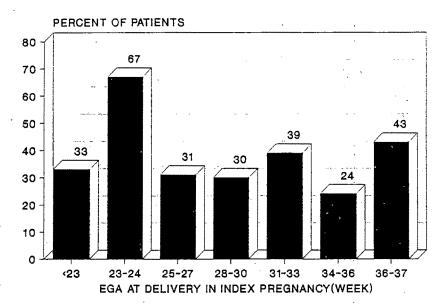

Fig. 3. Percent of patients with recurrent preterm premature rupture of membranes by estimated gestational age at delivery in index pregnancy.

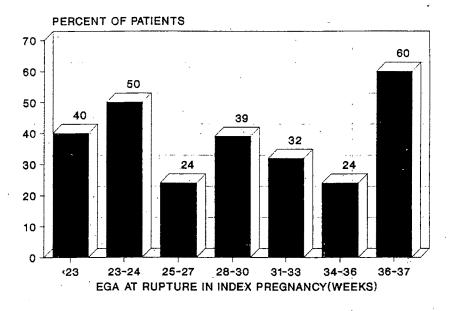

Fig. 4. Percent of patients with recurrent preterm premature rupture of membranes by estimated gestational age at rupture in index pregnancy.

delivered at our hospitals in their subsequent pregnancies would be different from patients delivered at other institutions.

Overall, the above data demonstrate that there is a significant tendency for preterm premature rupture of membranes to be repeated in consecutive pregnancies. We hope that this study will facilitate the counseling of patients with preterm premature rupture of membranes and help the clinician in identifying a group of patients in need of closer observation and

follow-up as part of an overall prematurity prevention program.

Renal pelvicalyceal dilation in antepartum pyelonephritis: Ultrasonographic findings

Diane Twickler, MD, a. b Bertis B. Little, PhD, a Andrew J. Satin, MD, and Charles E.L. Brown, MD

Dallas, Texas

The purpose of the present study was to determine whether pregnant women with pyelonephritis have differences of pelvicalyceal systems, compared with normal pregnant control subjects, that might predispose to upper urinary tract infection. Ultrasonographic examination of both kidneys in coronal and axial planes of 24 women with clinical pyelonephritis and positive urine cultures was compared with results in control subjects matched for gestational age, parity, and race. Women with right or bilateral pyelonephritis had increased dilation of the right calyceal system, compared with controls (1.7 cm vs 0.8 cm, p < 0.001). Renal pelvis volume was increased as well (29.3 vs 5.5 cm³, p < 0.001). Renal pelvicalyceal dilation in antepartum pyelonephritis was significantly increased compared with normal physiologic dilation of pregnancy. Follow-up nephrosonography in a small number of women (N = 10) after treatment of pyelonephritis did not reveal a consistent decrease in renal dilation, suggesting that dilation of the renal pelvis may antedate pyelonephritis. Further study of this phenomenon is warranted. (AM J OBSTET GYNECOL 1991;165:1115-9.)

Key words: Pyelonephritis, nephrosonography, hydronephrosis

Physiologic dilation (hydronephrosis) of the collecting system of the kidneys during pregnancy is a well-described entity. 1-3 Various causes have been proposed for this urinary obstruction or stasis, including dextrorotation of an enlarging uterus and dilatory effects of progesterone on the ureters. 4-6 Nephrologic ultrasonography of hydronephrosis, or pelvicalyceal dilation, during pregnancy has been reported by several inves-

tigators.⁷⁻¹¹ Greater dilation of the right kidney collecting system, compared with that of the left collecting system, is well documented.⁸⁻¹¹

Pyelonephritis complicates approximately 1% to 2% of pregnancies, although its incidence has decreased with routine detection of asymptomatic bacteriuria. ¹² Symptomatic pyelonephritis occurs more frequently in the right kidney, and this unilateral pattern appears to be related to urinary stasis and reflux. ^{12, 13} Certain characteristics of some of the infecting organisms play a role in the development of pyelonephritis. It is now recognized that the fimbriae of *Escherichia coli* promote adhesion to the urinary tract epithelium, allowing the bacteria to invade and multiply. This frimbria-specific, O-antigen type *E. coli* is the major pathogen in ascending pyelonephritis. ^{13, 14} Urinary stasis and pyelonephritis are clearly associated, but the correlation of upper

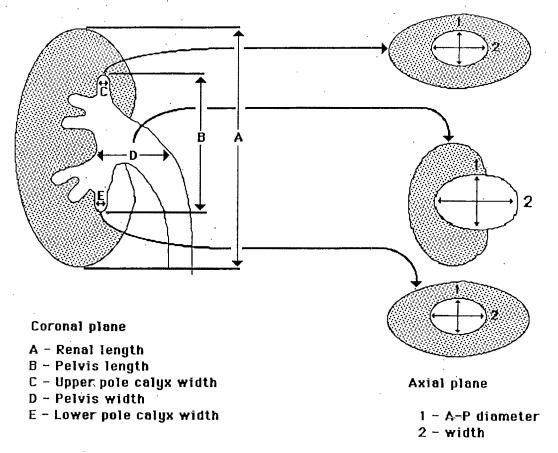

Fig. 1. Three-dimensional renal anatomy and parameters measured during nephrosonography.

urinary tract infections with the degree of collecting system dilation has not been delineated in pregnancy. Reports in the literature are conflicting, primarily because the renal collecting system dilation examined did not select exclusively for pyelonephritis but included urinary tract problems of various causes, including asymptomatic bacteriuria, and renal calculi.^{8, 11} The purpose of our prospective study was to determine whether pregnant patients with clinical pyelonephritis had renal pelvicalyceal dilation that was greater than normal physiologic dilation of pregnancy. Additional ultrasonographic characteristics of the kidney also were assessed.

Material and methods

Patients. Fifty-three pregnant women underwent 65 ultrasonographic examinations between July 1989 and September 1990. Twenty-seven women were admitted to the hospital with the diagnosis of acute pyelone-phritis. The criteria for this diagnosis were elevated temperature, flank pain, pyuria, and positive urine culture. White blood cell count, creatinine, and urine red blood cell count were recorded. Two of these women were readmitted for treatment of recurrent pyelone-phritis. Renal sonograms were obtained in these pa-

tients, for a total of 29 ultrasonographic studies within 24 hours of admission. Of these 29 examinations of 27 patients, two studies were eliminated when urine cultures were subsequently reported as negative and nephrosonography revealed renal stones. One ultrasonographic study was eliminated because crossedfused ectopia of the collecting system was diagnosed, for a total of 26 examinations of 24 patients included in our study. These 24 women were matched to controls for gestational age within 2 weeks (on the basis of ultrasonographic biometry), race, and parity. The controls were chosen on the basis of negative history for renal disease or treatment for asymptomatic bacteriuria, for which we routinely screen in our population. The confirmation of gestational age by ultrasonographic biometrics instead of last menstrual period was thought to be more reliable in our patient population. In addition, nine patients underwent 10 repeat sonography after intravenous hydration and antibiotic therapy were discontinued.

Ultrasonographic methods. Renal ultrasonographic examinations were performed with women placed in the right and left lateral decubitus positions with an UltraMark IV or VIII (ATL, Bothell, Wash.) ultrasonographic scanner equipped with 3 and 5 MHz me-

chanical sectors or annular transducers. Pelvicalyceal dilatation and renal pelvis volumes were determined in coronal and axial planes of the kidneys after bladders were empty (Fig. 1). Patients with full bladders voided. In the coronal plane the renal pelvis length, kidney length, and greatest widths of the upper-pole calyx, lower-pole calyx, and renal pelvis were determined. In the axial plane the greatest anteroposterior and width dimensions of the upper and lower pole calyces and renal pelvis width were measured. The greatest pelvicalyceal dilation in the coronal and axial planes were compared. In addition, renal pelvis volume was determined by the ellipsoid formula proposed by Cietak9: Volume = Length × Width × Thickness (anteroposterior plane) × 0.5223. Measurements of the renal pelvis in our study were altered from those of Cietak and Newton not to include the entire echogenic portion of the pelvis; only those sonolucent regions within the pelvis that were thought to represent the collecting system were included (Fig. 1). The overall appearance of the renal parenchyma was assessed to evaluate for any focal lesions or changes in general pattern of echogenicity.

Of the 26 studies performed on symptomatic patients with urine culture-positive pyelonephritis, 20 had right-sided symptoms, four had bilateral symptoms and two had left-sided symptoms. Ultrasonographic measurements of the collecting system in patients with right and bilateral symptoms (n = 24) were compared with those of matched controls by means of analysis of variance with the Student-Newman-Keuls test. In addition, repeat sonograms (n = 10), which were obtained in nine women with pyelonephritis after the discontinuation of intravenous hydration and antibiotics, were evaluated with paired test analysis. A statistical analysis was performed with SAS version 6.04 (Statistical Analysis System, SAS Institute, Cary, N.C.) on an AST 386 (AST Research, Inc., Irvine, Calif.) computer.

Results

Of the 24 patients with pyelonephritis, nine were white, nine were Hispanic, and six were black. Fourteen patients were nulliparous, whereas 10 patients had had one or more children. Sixteen patients had body temperatures >38° C, whereas eight had normal temperatures during hospitalization. Eighteen patients had an elevated white blood cell count, i.e., $>10.9 \times 10^9/L$. Eighteen catheterized urine cultures were positive for E. coli (>10⁵ organisms), three had Proteus mirabilis (>10⁵ organisms), and three had Klebsiella pneumonice (>10⁵ organisms). Serum creatinine was 1.0 mg/dl in one patient and 1.2 and 1.3 mg/dl in another patient with pyelonephritis on two separate admissions, while the creatinine level of the remaining 22 patients fell below 1.0 mg/dl.

Of the 26 nephrosonographic examinations performed on 24 patients, results in 24 were compared with those of matched controls in those patients with right (n = 20) or bilateral (n = 4) flank pain. Among pregnant women with pyelonephritis involving the right or both kidneys (n = 24), the right renal pelvis volume was significantly increased compared with that of matched pregnancy controls (29.3 vs 5.5 cm³, p < 0.001). In addition, the maximal calyceal dilation was significantly increased (1.7 vs 0.8 cm, p < 0.001) (Fig. 2 and Table I). Maximal area dilation of the calyceal system in the axial plane also was significantly increased among patients with symptoms compared with controls (p < 0.001).

Patients with acute pyelonephritis and left flank pain (n = 2) or bilateral findings (n = 4) were not analyzed because of small numbers. A comparison of left-kidney

[†]Renal pelvis volume (in cubic centimeters) = Length × Width × Anteroposterior diameter × 0.523.

[‡]Maximal dilation in coronal plane (in centimeters).

Axial plane area (in square centimeters) = Anteroposterior diameter \times Width.

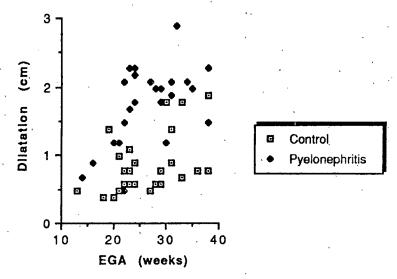

Fig. 2. Maximum calyceal dilation of right kidney in coronal plane versus gestational age. GA, Estimated gestational age.

pelvicalyceal measurements in patients with only right-sided acute pyelonephritis (n=20) compared with those of matched controls revealed that the left renal pelvis volume was significantly increased in patients with symptomatic right pyelonephritis (5.9 vs 2.2 cm³, p < 0.001). A statistically significant difference in maximal calyceal dilation between the patient and control groups occurred, but because the actual difference was <3 mm, the result was not clinically significant. No statistically significant difference was found in the area of maximum dilation in the axial plane of the calyces on the left side between patients with only right-sided symptoms and controls.

Nine women underwent 10 follow-up nephrosonographic examinations between 2 and 30 days after termination of intravenous antibiotics and hydration. In four cases the maximal calyceal dilation on the symptomatic side increased between 1 and 3 mm, when compared with the hospital admission sonogram. In three cases the calyceal dilation decreased between 1 and 4 mm, and there was no change in three cases. The renal pelvis volume of the right and left sides demonstrated no statistically significant change with *t* test analysis. Assessment of the ultrasonographic characteristics of the renal parenchyma revealed no focal or global changes. Focal nephritis and perinephric fluid collections were not apparent.

Comment

Stasis in the urinary collecting system and the development of an ascending urinary tract infection are clearly associated, but consistent findings of renal pelvis dilation in association with acute pyelonephritis in this study are new. In our study the clinical presentation of pyelonephritis is similar to that previously reported with right-sided symptoms occurring most frequently.

followed less commonly by bilateral symptoms and then left-sided symptoms, which are the least common. Increased dilation of the right collecting system in pregnant patients with right or bilateral pyelonephritis compared with that of matched controls was statistically significant. This was demonstrated in the maximal polar pelvicalyceal dilation in the coronal plane, the maximal polar pelvicalyceal area in the axial plane, and pelvicalyceal volumes, determined by the ellipsoid formula.

Interestingly, there was a statistically significant increased dilation of the left renal pelvis in patients with right-sided pyelonephritis, although the actual leftsided volumes were much less than the right-sided dilation. However, this was not reflected in the polar pelvicalyceal measurements. As a possible explanation of these findings, patients with pyelonephritis have bilateral renal pelvis dilation with the right more dilated than the left. Greater dilation on the right side would possibly increase the likelihood that this side would become infected with an ascending process. Alternatively, both kidneys were infected, but infection on the left side was not as severe as that on the right; therefore symptoms were less severe on the left. This latter speculation is actually supported by radiologic findings in one study, which found bilateral renal abnormalities with intravenous pyelograms in spite of clincial symptoms on one side.15 It was concluded that there may be clinically silent involvement of the opposite kidney.

Three patients were eliminated from the study group because of renal complications other than pyelonephritis. Ultrasonography detected previously unknown renal pelvis calculi in two of these patients and one congenital anomaly, fused pelvic kidneys. The findings had important implications for clinical management.

Patients being treated for pyelonephritis are given intravenous antibiotics and hydration.16 The effect of intravenous hydration on the collecting system may confound the findings of our study. Adequate hydration should not affect the upper urinary tract dimensions if the bladder is empty.17 The normal creatinine level in all but two patients suggests adequate hydration. Our follow-up evaluations of nine pregnant patients with 10 sonograms, after the intravenous supplementation and antibiotic therapy were discontinued, demonstrated no trend in a small series. Renal pelvis volume of either side did not change, and the pelvicalyceal dilation of the upper or lower pole of the involved kidney(s) changed very little, a difference probably not greater than measurement error (≤ 3 mm).

There is extensive mention in the literature about the radiographic appearance of pyelonephritis in nongravid patients. Early studies based on excretory nephrograms revealed normal kidneys in 75% to 80% of patients.15 Most abnormalities were parenchymal changes with pelvic dilation in five of 40 patients and calyceal dilation in three of 40 cases. In six patients undergoing computed tomography and ultrasonography in one study¹⁸ and two patients having ultrasonography in another,19 no hydronephrosis was seen. Friedland et al.20 believe hydronephrosis is not present with ultrasonography in acute pyelonephritis and, if seen, should raise the possibility of pyonephrosis, a serious complication with implications for management, including drainage. These findings suggest hydronephrosis on ultrasonography is an uncommon sequela of acute pyelonephritis in the nonpregnant patient population.

It appears that hydronephrosis, more than the normal physiologic dilation of pregnancy, is found in antenatal pyelonephritis; this hydronephrosis is rarely seen as an ultrasonographic finding in the nonpregnant population. Given the knowledge that physiologic dilation of pregnancy is commonplace and pyelonephritis is increased in the pregnant populations, one may speculate that a greater degree of dilation may be a risk factor for development of pyelonephritis.

The results of this study have important clinical implications. If the dilation antedates the onset of pyelonephritis, the potential for screening populations at risk may exist. A further longitudinal study of patients with serial nephrosonography of a randomly selected cohort of pregnant women to determine whether the dilation

precedes the development of upper urinary tract infection is needed.

Doppler flow velocities in single umbilical arteries

Norman B. Duerbeck, MD, Marcello Pietrantoni, MD, Kathryn L. Reed, MD, Caroline F. Anderson, RDMS, and Lewis Shenker, MD

Tuscon, Arizona

Fetal compromise has been associated with an umbilical artery waveform pattern of low or absent diastolic velocity relative to systolic velocity. Fetuses with single umbilical arteries have an increased risk of major malformations, mortality, retarded fetal growth, and prematurity. In this study Doppler flow velocities were obtained in 13 fetuses (four twin fetuses and nine singletons) with a single umbilical artery. Five (38%) fetuses, consisting of four singletons and one twin, had anomalies. Six (46%) fetuses were small for gestational age, including two twin fetuses and three singleton fetuses with anomalies. Three (23%) of the 13 systolic-to-diastolic velocity ratios were abnormally high. Whereas this is a higher rate of abnormal ratios than the reported 2% to 3% in control populations, it is interesting to note that 77% of fetuses with single umbilical arteries had normal systolic-to-diastolic ratios. (AM J OBSTET GYNECOL 1991;165:1120-2.)

Key words: Single umbilical artery, Doppler flow velocities

Doppler ultrasonography has provided a means to perform noninvasive assessments of blood flow in fetal and placental vessels.1-6 As pregnancy progresses, there is a steady decline in umbilical artery ratios of systolicto-diastolic velocities. This decline has been attributed to a decrease in the resistance of umbilical circulation.4 It has been demonstrated that fetal growth retardation may be associated with persistently elevated systolic-todiastolic ratios after 30 weeks.1, 3, 5 As more umbilical artery flow velocity data become available from an everexpanding list of pathologic states, such as trisomy 13 and 18 and dizygotic and monozygotic twins, 4, 6 the question arises whether there is a high relative risk for abnormal systolic-to-diastolic ratios in single umbilical arteries compared with three-vessel cords.

Fetuses with a single umbilical artery are at increased risk for unfavorable outcome.7-10 In a study by Bryan and Kohler,10 143 of 20,000 infants had a single umbilical artery, giving a rate of 0.72%. Of these, 18% had major malformations, 34% were small for gestational age (SGA), and 17% were delivered preterm. Given the association of a single umbilical artery and the increased potential for perinatal morbidity and mortality, we examined Doppler flow velocities in two-vessel umbilical cords.

From the Department of Obstetrics and Gynecology, University of

formed, 13 patients with single umbilical arteries were examined with two-dimensional and Doppler ultrasonography. All studies were performed with a 3.5 or 5.0 MHz transducer. The indications for ultrasonography on those patients with a single umbilical artery included twin gestation for concordant growth, low maternal αfetoprotein levels, fundal height less than dates, and family history of encephalocele. Gestational age at the time of ultrasonography varied from 22 to 38 weeks. Single umbilical artery on ultrasonography was an incidental finding, and in most instances serial Doppler flows were not obtained. In three fetuses serial values were obtained, and in these cases the most recent result was reported. The systolic-to-diastolic ratios did not change significantly with time in this group. In twin gestations only the fetuses with a single umbilical artery showed an abnormal systolic-to-diastolic ratio; outcomes of twins with normal ratios are not described. In all instances standard ultrasonographic measurements were performed, including biparietal diameter, femur length, abdominal circumference, and amniotic fluid volume estimation. Gestational age was estimated from fetal size when menstrual dates were unknown or inaccurate. SGA was defined as birth weight <10th percentile by institutional standards. An abnormal Doppler systolic-to-diastolic ratio was defined as >95% confidence interval for gestational age.4 After identification of a single umbilical artery, the umbilical artery flow velocity waveform was obtained with a 3.5 MHz transducer with pulsed Doppler capability. With page-print outputs from a strip chart recorder, maximal velocity was measured from the 0 line to the highest part of the velocity peak (systole). Minimal velocity was measured at the nadir after the peak (diastole). A ratio of systolic peak to diastolic nadir was calculated. Umbilical artery pulsed Doppler waveforms were recorded for at least 8 to 10 beats. Fetuses were exposed to <46 mW/cm²

power density according to manufacturer's specifica-

Management of the fetuses was carried out without knowledge about the Doppler information. At the time of birth, method of delivery, Apgar scores, weight, presence of meconium, presence of congenital anomalies, and admission to the neonatal intensive care unit were recorded.

Results

Nine singletons and four twins were included in this series. Maternal age was 23.9 ± 4.4 (mean ± SD), gravidity was 2.4 ± 1.3 , and parity was 1.4 ± 1.1 . Three of 13 (23%) patients underwent cesarean section. Indications for cesarean section were elective repeat cesarean section, failed trial of labor after previous cesarean section, and breech presentation. One fetus with a chromosome abnormality did not survive. There were no instances of fetal distress as defined by late decelerations detected by electronic fetal monitoring. As shown in Table I, in live-born infants, there were no 5-minute Apgar scores <7. Gestational age at the time of delivery was 36.4 ± 3.4 weeks with a mean birth weight of 2383 \pm 908 gm. In the twin fetuses there was one example of discordant growth in a fetus with a single umbilical artery and an elevated systolic-todiastolic ratio of 4.7. In spite of discordant growth the smaller twin was not SGA. Meconium was present in one instance in a breech delivery by cesarean section; this fetus had an systolic-to-diastolic ratio of 2.2.

Five of 13 (38%) of fetuses had congenital anomalies. None of these had abnormal systolic-to-diastolic ratios. The anomalies included gastroschisis, occipital encephalocele, congenital cytomegalovirus infection, right renal agenesis, and triploidy. Of six SGA fetuses, one had an elevated systolic-to-diastolic ratio. Of three fetuses with abnormally high systolic-to-diastolic ratios, one was SGA. The only intrauterine fetal death was in the fetus with a 69,XXY karotype at 25 weeks.

Comment

In this study we measured umbilical artery velocity in fetuses with a single umbilical artery. As pregnancy progresses, there is normally a steady decline in the umbilical artery systolic-to-diastolic ratio. This decline is theoretically caused by decreasing vascular resistance.4 A persistently elevated systolic-to-diastolic ratio may be associated with fetal growth retardation1. 2, 4, 5 and in some fetuses with congenital anomalies.8,6

It is well established that fetuses with a single umbilical artery are at increased risk for intrauterine growth retardation or congenital anomalies. Bernirschke⁸ found single umbilical arteries in 0.85% of singletons and 5% of twin gestations. Thirty-nine percent of the infants with one artery had associated anomalies. Other investigators quote a mortality rate as high as 14% in infants with a single umbilical artery.9 In addition, single umbilical arteries occur more often in diabetic pregnancies and in spontaneous abor-

In this small sample size there was no clear correlation between abnormally elevated systolic-to-diastolic ratios and SGA fetuses. The 17% sensitivity in this group is not surprising given the quoted sensitivity of Doppler in identifying growth retardation in large series of only 50% to 60%.4 It is interesting to note that none of the fetuses with congenital anomalies in this study had abnormal systolic-to-diastolic ratios, although

in larger series of fetuses with congenital anomalies the incidence of abnormal systolic-to-diastolic ratios is 50%. Three of the thirteen fetuses studied had abnormal systolic-to-diastolic ratios for a rate of 23%; this incidence is nearly 10 times the rate cited in control populations. It is interesting to note that in a situation in which the number of umbilical arteries was reduced from two to one, Doppler flow velocity ratios through these single umbilical arteries were normal in 77% of cases.

Impact of prenatal testing on maternal-fetal bonding: Chorionic villus sampling versus amniocentesis

N. Caccia, BSc, J.M. Johnson, MD, G.E. Robinson, MD, and T. Barna, BSc

Toronto, Ontario, Canada

The process of maternal-fetal attachment, considered vital for normal infant development, begins during pregnancy and can be affected by a number of external factors. In this study the impact of prenatal testing on maternal-fetal bonding was evaluated in 253 women undergoing either first-trimester chorionic villus sampling (n=101) or second-trimester genetic amniocentesis (n=152). The women were evaluated by means of a modification of the Cranley Maternal-Fetal Attachment Scale, administered before and after the results of the prenatal diagnostic testing were made known to them (mean gestational ages of 10.6 and 15.7 weeks for the chorionic villus sampling group and 16.5 and 21.1 weeks for the amniocentesis group). The results showed: (1) that maternal-fetal attachment begins as early as 10 weeks' gestation and increases significantly as the pregnancy progresses, (2) that maternal-fetal attachment increases significantly, once the results are known to be normal, for both groups (p < 0.001), (3) that this increase occurs about 5 weeks earlier for patients with chorionic villus sampling in comparison to those undergoing amniocentesis (p < 0.001). Thus, with regard to the process of maternal-fetal attachment, first-trimester chorionic villus sampling appears to be preferable to second-trimester amniocentesis. (AM J OBSTET GYNECOL 1991;165:1122-5.)

Key words: Maternal-fetal bonding, prenatal diagnosis, chorionic villus sampling, amniocentesis

Johnson, MD, Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, 200 Elizabeth St., 6EN-216, Toronto, Ontario, Canada M5G 2C4. 6/6/31198 The process of maternal-infant bonding, considered vital for normal infant development, has been shown to begin during pregnancy and can be affected by a number of external factors. ¹⁻³ While the bonding process in the later stages in pregnancy (>20 weeks' gestation) has been well investigated, ³⁻⁴ the extent to which bonding is manifest in early pregnancy (<20 weeks'

gestation) and the factors affecting this bond remain unclear. Prenatal diagnosis has been shown to have a significant effect on the emotional and psychologic components of pregnancy,5-7 but its impact on the bonding process in early pregnancy has not been previously investigated. Since the period of undergoing prenatal diagnosis and awaiting the results is associated with significant parental anxiety,8-10 it is possible that prenatal diagnosis may interfere with or delay this bonding process.

The purpose of this study was to evaluate maternalfetal bonding in early pregnancy to determine: (1) whether maternal-fetal bonding can be demonstrated before 20 weeks' gestation and (2) the effect of prenatal diagnosis on maternal-fetal bonding, specifically, whether bonding is delayed in patients who undergo amniocentesis as opposed to chorionic villus sampling (CVS).

Material and methods

The study group consisted of women with singleton pregnancies, confirmed by ultrasonography, with appropriate indications for prenatal testing according to the Canadian Guidelines for Prenatal Genetic Diagnosis.11 Eligible patients underwent nondirective genetic counseling regarding the risks, benefits, and limitations of chorionic villus sampling and/or amniocentesis and provided informed consent for their procedure of choice and for participating in the study.

The women were evaluated by means of a modification of the Cranley Maternal-Fetal Attachment Scale, ¹² administered before (preresult questionnaire) and after (postresult questionnaire) their results were made known to them. The Maternal-Fetal Attachment Scale allows patients to rank statements of their feelings about the pregnancy and the fetus in five areas of attachment: interaction with the fetus, giving of self, roletaking, differentiation from self, and attributing characteristics to the fetus. The statements are ranked on a scale from 1 to 5, with 5 being the most attached or bonded. In this study the scale was modified by omitting the category of "attributing characteristics to the fetus" because the questions were not appropriate for a gestational age <20 weeks.

The effect of ultrasonography on maternal attitudes toward the pregnancy and fetus were examined by asking the patient to rank a series of statements on a scale of 1 to 5 with 5 indicating the greatest effect.

The data were analyzed and statistical analysis, where appropriate, was by paired two-tailed Student t test with p < 0.05 being considered significant.

Results

Over the 4-month period beginning May 1989, 253 consecutive women undergoing chorionic villus sam-

pling (n = 101) or second-trimester genetic amniocentesis (n = 152) met the entry criteria. The groups did not differ significantly with respect to age, parity, socioeconomic status, or level of postsecondary education. Their indications for prenatal testing are described in Table I. A 100% follow-up rate was achieved in both groups.

The preresult and postresult questionnaires were administered to the patients at an average gestational age of 10.6 and 15.7 weeks for the CVS patients and at 16.5 and 21.1 weeks for the amniocentesis patients. This resulted in three comparison groups being generated: the preresult and postresult CVS group (group 1), the postresult CVS and preresult amniocentesis group (group 2), and the preresult and postresult amniocentesis group (group 3). In all three groups the level of bonding was significantly higher in the postresult group than in the preresult group (p < 0.001) (Table II). This increase in bonding occurred approximately 5 weeks earlier in patients undergoing CVS compared with those undergoing amniocentesis (Fig. 1).

There was an appreciable level of bonding (3.8 on a scale of 5) present in all preresult patients with no statistical difference between amniocentesis and CVS patients, in spite of a difference in gestational age of almost 6 weeks (Fig. 1). Similarly, the postresult levels of bonding did not differ significantly, with the postresult CVS patients achieving the same level of bonding by 15 weeks as the postresult amniocentesis patients achieved at 21 weeks (p < 0.001) (Table II).

All of the patients underwent one or more ultrasonographic examination(s) in association with their procedures. In 126 of 253 patients (50%), seeing the fetus on ultrasonography made them feel less anxious about the pregnancy and closer to the baby (72%), made the baby seem more real (87%) and in some cases made them feel "more like parents" (27%). As may be expected, positive feelings also made a significant percentage of the parents (55%) feel more anxious about the possibility of an abnormal result. These reactions were stronger at earlier gestational ages (≤12 weeks'

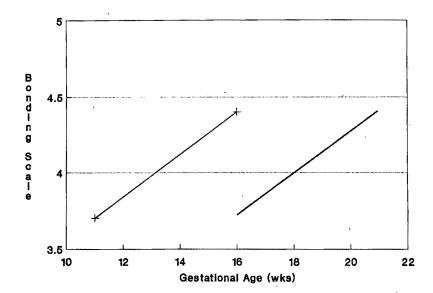

Fig. 1. Maternal-fetal bonding: CVS versus amniocentesis. Maternal-fetal bonding increased significantly in both CVS patients (thin line) and amniocentesis patients (thick line) once results of testing were reported to be normal (15.7 weeks' gestation for CVS patients, 21.1 weeks for amniocentesis patients). This increase in bonding occurred approximately 5 weeks earlier in CVS patients. Bonding scale is from 1 to 5 with 5 representing greatest bonding.

gestation), although they also were present at later stages (13 to 20 weeks' gestation). We found that the first sonogram tended to have the greatest effect on their feelings toward the pregnancy, although subsequent sonograms also had an effect.

Comment

Our results indicate that in patients undergoing prenatal diagnosis, maternal-fetal bonding can be demonstrated as early as 10 weeks' gestation and increased significantly once the test results are known to be normal. This is consistent with previous studies that have shown that women undergoing prenatal diagnosis are reluctant to become "involved" in their pregnancies until their fetuses are known to be normal. This reluctance also may explain why, in these patients, bonding

appears more a function of the prenatal diagnosis experience than of gestational age. In this study the postresult CVS patients were shown to be significantly more bonded than were the preresult amniocentesis patients, in spite of being at a similar gestational age. Once the results were known to be normal, the level of bonding in CVS patients and amniocentesis patients was similar, suggesting that this factor plays a major role in the development of bonding in these patients. Previous investigators hve shown that CVS and amniocentesis patients have similar levels of attachment by the late second trimester,9 suggesting that CVS offers no long-term benefit in maternal-fetal bonding compared with amniocentesis. However, amniocentesis patients have been shown to be more bonded than gestational agematched controls once they know their fetuses are

p < 0.001, when compared with preresult bonding (paired two-tailed Student t test).

normal⁷; this seems to indicate that prenatal diagnosis may increase maternal-fetal bonding earlier in gestation. Maternal-fetal attachment has been shown to alter maternal life-styles to be more beneficial to the fetus³; therefore it is possible that an earlier increase in bonding may be beneficial by positively influencing maternal behavior at an earlier stage in pregnancy, when it may have a more significant effect on fetal outcome.

One of the factors that likely affects maternal-fetal bonding is maternal anxiety. Anxiety has been shown to correlate with the somatic symptoms of pregnancy and gestational age, as well as inversely with maternal education.18 Studies evaluating the effect of prenatal diagnosis on maternal anxiety have shown that CVS patients demonstrate an earlier reduction in maternal anxiety than amniocentesis patients.9, 10 The reduction parallels the increase in attachment we found and may have been a factor facilitating the ease and degree of bonding observed in our patients. The effect of prenatal diagnosis on third-trimester anxiety is unclear, although Marteau et al.6 reported that in patients who have undergone prenatal diagnosis, anxiety levels in the third trimester fall or remain the same as in the second trimester, whereas in the general population anxiety levels increase in the third trimester.

Preresult anxiety levels have been shown to be lower in patients whose primary indication for prenatal diagnosis is late maternal age compared with other indications.14 In this study later maternal age was the primary indication for prenatal diagnosis in 117 of 151 amniocentesis patients (77%) and 72 of 102 CVS patients (71%). Preresult binding levels in this subpopulation were evaluated and compared with levels in the remaining patients. No significant differences were found, suggesting that maternal-fetal bonding in prenatal diagnosis patients is not influenced by the indication for the procedure in spite of possible differences in preresult anxiety levels.

The influence of ultrasonography on maternal attitudes toward the fetus were significant, with patients reporting that seeing the fetus on a sonogram made them feel less anxious about the fetus but more anxious about the possibility of an abnormality; overall the ultrasonography engendered positive feelings toward the pregnancy. It is likely that the ultrasonographic examination performed immediately before the preresult bonding evaluation may have contributed to the significant bonding levels found at the time of the procedure.

We conclude that in patients undergoing prenatal genetic testing, maternal-fetal bonding can be demonstrated as early as 10 weeks' gestation and increases significantly once test results are known to be normal. Seeing the fetus on ultrasonography and being informed of normal results were important factors influencing the development of this bonding. The increase in bonding occurred approximately 5 weeks earlier in patients undergoing CVS compared with those undergoing amniocentesis, suggesting CVS may be preferable to amniocentesis with respect to the process of maternal-fetal bonding.

The pathology of maternal mortality

D.R. Shanklin, MD,^a Sheldon C. Sommers, MD,^b Dick A.J. Brown, MD,^c Shirley G. Driscoll, MD,^d and John Figgis Jewett, MD^c†

1.0 Introduction

1.1 Scope

Properly construed, the pathology of maternal mortality links the concepts of (1) gestational pathophysiology and (2) pathogenesis of lethal lesions. In this context, "lesion" is to be read as ultrastructural and chemical derangement, as well as those histologic changes in tissue traditionally examined and classified by anatomic pathologists. We anticipate that in time better tools will become available to study these matters at fundamental levels of life function. For purposes of this discussion we will describe in some detail those pathologic conditions in our recent experience that caused maternal death in Massachusetts during the 20-year period 1966. to 1985 as representative of current epidemiologic and clinical concerns. This is part of a series of about 1100 maternal deaths that will be reported in further detail elsewhere. We add other cases to illustrate the range of lesions possible under various conditions. The variation of lesions will be emphasized. Maternal death, as a matter of general public health interest, touches numerous other aspects of medicine, obstetrics, and pa-

Mammalian pregnancy, a natural and healthy state, represents the culmination of multiple adaptations of

structure and function. Either or both may predispose to lesion formation. Some of these are unique to pregnancy; others are not, with a varied influence of pregnancy. There are three degrees of gestational influence in the latter group: The first is those conditions that although intercurrent, are enhanced by pregnancy. The second is a group in which pregnancy is a minor or uncertain factor in progression or prognosis. The third is those fully intercurrent, occurring on the same apparently random basis in pregnant women as in the population at large without evidence of mutually adverse effects on pregnancy from the maternal point of view.

Nevertheless, our experience in reviewing this series of 281 maternal deaths suggests that some cases cannot be classified in such a straightforward fashion. The clinical attributes of each topic in the classification scheme will be developed as a composite to the extent possible. The reader should keep in mind that these profiles are not exclusive statements of possible signs or symptoms. As a further contribution to this understanding, we include brief abstracts of one or more case histories with each of the major categories. These abstracts illustrate both specific features of individual cases and provide diagnostic criteria for assignment of cause.

1.2 Historical overview

The current era of professional and public concern over maternal mortality must be considered to have begun with the reported work of Semmelweis. 42 This historical perspective is at root an exercise in pragmatism in that his preventive modality for puerperal sepsis antedated by a generation a proof of the germ theory of certain infectious diseases,18 including puerperal sepsis itself. Subsequently, further general improvement in the maternal mortality rate followed specific developments in anesthesia, blood banking, antimicrobials, and systematized prenatal care.32,40 However, in the opinion of the senior author, the epitome of this approach became manifest when it was integrated with evolving concepts of clinical pathophysiology exemplified by the leadership in Massachusetts of the late Dr. John Figgis Jewett. When the working party (Shanklin and Sommers) sought access to the Massachusetts Maternal Welfare Committee records

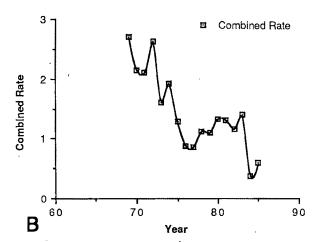

Fig. 1. Number and rates of maternal mortality. A, Graphic depiction of number of maternal deaths in Massachusetts, 1954 to 1985. Note sharp decline in absolute number of cases from 1965 (56 cases) to 1966 (24 cases). B, Graphic depiction of rates of maternal deaths in Massachusetts, 1969 to 1985. Note further decline in rate with the additional reduction in absolute numbers in the equivalent section of part A. Combined rate is maternal deaths per 10,000 live births plus still births (total parity). The rates for 1969 to 1974 ranged from 1.597 to 2.7 per 10,000; the rates for 1975 to 1985 ranged from 0.371 to 1.277 per 10,000.

for this survey, Dr. Jewett gladly approved it. Sadly, just a few months after we began the review, John Jewett died.

1.3 Sample selection

As we worked our way deeper into the records, it became clear that a modern period of 20 years (1966 to 1985) existed that qualified for special emphasis on the following grounds:

A. A charting of the numbers of cases occurring per year in the Commonwealth over the interval 1948 to 1985 revealed a clear and gratifying decline between 1964-65 and 1966-67, against little change in total

annual births, with a further reduction since then (Fig. 1).

- B. As the most recent period, it was considered to more effectively represent those diseases and disorders likely to occur in the population in the near future.
- C. As the most recent period critically examined by both the committee and the working party, it had a better chance of relevance to current methods of diagnosis and treatment.
- D. The period still had 281 maternal deaths, a sample far in excess of what any given practice or hospital might have available for study.
- E. By the 1960s the Committee had become accepted and institutional cooperation in the provision of information and documentation to the field investigators was at a high level. This salutary state of affairs was due to the efforts of Dr. Jewett and the Committee, much enhanced through publication of selected case reports in the *New England Journal of Medicine* carefully, critically, and fairly analyzed.

1.4 Study methods

The residuary files were systematically reexamined year by year by the working party, and data records were put into a prepared microcomputer file scheme. Remnant information by which individual persons could be identified was omitted from the computer data base. After preliminary classification by various obstetric concerns (e.g., section versus vaginal birth, labor management, anesthetic use, pregnancy age, puerperal survival), the cases were rearranged by gross clinicopathologic criteria into arenas to be described.

2.0 Working definition of maternal mortality

2.1 Definition developed from this study

The working party proceeded independent of any particular definition of what constitutes a maternal death, preferring to let the accumulated experience speak for itself. The committee had quite obviously used a comprehensive, inclusive definition and was assiduous in ferreting out cases and information.⁴⁰

During this preliminary assessment of the data, it became apparent that 120 days postpartum would be the most directly useful upper cutoff time interval other than for gestational trophoblastic disease. As will be developed, some pregnancy-related conditions did not prove to be lethal until later, but as a practical procedural definition, maternal death is one in which a woman dies while bearing or just relieved of conceptual tissues or dies up to 120 days after the passage of placental sac, embryo, fetus, or child. It will be seen that this definition includes women dying of chorioma or choriocarcinoma inclusive of complications of their treatment over time. More recently, Allen, Chavkin, and Marinoff¹ used 6 months as a time-specific puerperal interval for inclusion as a maternal death.

Table I. Perinatal mortality in 281 cases of maternal mortality

Conceptual sacs		285*
Ectopic pregnancies	9	
Maternal deaths related to early pregnancy termination	4	
Presumptively viable fetus dying with mother	49	
Subtotal, antenatal maternal deaths		62
No embryo (choriomatous neo- plasm)		6
Less case adjustment subtotal		$\overline{68}$
Puerperal maternal deaths	(net)	217
Fetus stillborn	52	(23.96%, of 217)
Neonatal death	19	(8.76%)
Neonatal survival	145	(66.82%)
Outcome unknown	1	(

^{*}Includes two sets of twins and one of triplets; one twin gestation (Miniabstract 14) resulted in a living infant and a fetus dying with the mother. The latter has been ignored for purposes of determining the perinatal death rate among puerperal maternal deaths.

2.2 The American College working definition

This should be compared with the current form of the consensus statement provided by the American College of Obstetricians and Gynecologists (ACOG) in cooperation with a number of other interested organizations under the title: "Standard terminology for reporting of reproductive health statistics in the United States2:"

Maternal death: The death of a woman from any cause related to or aggravated by pregnancy or its management (regardless of duration or site of pregnancy) but not from accidental or incidental causes.

Direct obstetric death: The death of a woman resulting from obstetric complications of pregnancy, labor, or the puerperium; from interventions, omissions, or treatment; or from a chain of events resulting from any one of these.

Indirect obstetric death: The death of a woman resulting from a previously existing disease or a disease that developed during pregnancy, labor, or the puerperium that was not due to direct obstetric causes, although the physiologic effects of pregnancy were partially responsible for the death.

The ACOG statement went on to limit indirect obstetric death in the following note: "Death occurring to a woman during pregnancy or after its termination from causes not related to the pregnancy nor to its complications or management is not to be considered a maternal death. Nonmaternal causes may result from accidental events (e.g., auto accident or gunshot wound) or incidental causes (e.g., concurrent malignancy).2"

The consideration that went into the ACOG definition notwithstanding, the working party came to a different perspective. The influence of pregnancy on intercurrent disorders and vice versa may be subtle or simply not yet known. Accordingly, we propose that all deaths closely related in time to pregnancy be included as the point of origin of concern and investigation. Dr. Jewett's committee very clearly used essentially this approach and for good reason. After close review, the working party concluded it could not dismiss accidents or homicides as maternal deaths because psychologic factors derived from pregnancy or puerperium may have been significant contributory or even proximate causes of the deaths just as much as physiologic factors or specific diseases might be in others. This point will be further considered later.

3.0 Perinatal mortality within maternal mortality

3.1 Net sample size

These 281 mothers carried 285 conceptual sacs. The excess is due to two sets of twins and one set of triplets. Consideration of true perinatal mortality under these circumstances requires an adjustment to find the number of fetuses and newborns at independent risk born before maternal death and several other aspects of the matter. This is shown in the upper part of Table I. Note that the overall fetal loss from women dying antenatally was a substantial 16.9% (48 of 284). The rest of the difference is accounted for by (1) lack of embryo (choriomatous neoplasm), (2) ectopic pregnancy, or (3) maternal death related to pregnancy termination. There was one case lacking fetal outcome.

3.2 Perinatal mortality

The overall perinatal mortality rate was 32.7%, of which about three quarters were stillborn (23.9%) and one quarter were neonatal deaths (8.8%). The data are provided for comparison with the perinatal outcome in the various subcategories of maternal death discussed below.

4.0 Classification of maternal mortality

4.1 Arrangement of the classification

The entire series of 281 maternal deaths was closely examined for the appearance of related points in history, course, outcome, and autopsy findings. These led in all but one case to a summary statement of the central pathophysiologic theme of each case. During the summarizing assembly of these themes, it became apparent that significant supportive themes or findings were often present that warranted inclusion as secondary points in the classification to be presented. Sections 4.2, 4.3, and 4.4 contain the three primary groups in the order noted above (Section 1.1) listed by primary and secondary attributes. In some instances a combination of secondary attributes is given. Numbers in parentheses indicate when more than one case fits the combined primary and secondary criteria.

- 4.2 Group one: Conditions unique to pregnancy (83 cases; 29.54%)

5.0 Mortal conditions unique to human gestation

5.1 General

This group accounted for 83 of the 281 cases or 29.54% of all maternal deaths for the 20-year period. Assignment here was on the reasonable basis that gestational changes in the reproductive tract; the presence of conceptual products; and clinical efforts at diagnosis, management, or treatment were and are, by self-definition, unique to pregnancy. Thus disseminated intravascular coagulation, a difficult diagnostic syndrome induced by many pathologic processes, is best classified here through its link to amniotic fluid infusion of embolism. The task then, for that condition as an example, becomes one of understanding the variety of pathogenetic mechanisms by which the normally salutary physical and chemical buffering effects of amniotic fluid are cast aside and disaster strikes.

The mortal conditions related to abnormal implantation are obvious: Ectopic pregnancy remains difficult to identify and manage, abruptions still occur, and placenta previa with or without accreta has not been eliminated. The questions of causality of toxemia, better known in Europe as gestosis, are less rancorous with newer insights on the role of nutrition, metabolic injury, and atypical renovascular responses to pregnancy, 19, 46 but severe forms of the disorder remain a major factor in maternal death. 10 Despite generally effective che-

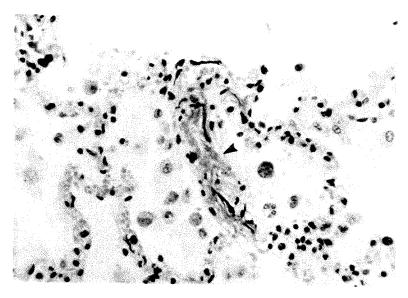

Fig. 2. Amniotic fluid embolization. Peripheral lung parenchyma showing elongate cluster of transported squamous cells and a small, recent segmental thrombosis (arrow). (Hematoxylin and eosin; original magnification ×250.)

motherapy against chorionic malignancy, the problem has not gone away. Finally, treatment or medication during pregnancy and labor remain occasional sources of serious injury and, sometimes, death. The relative frequencies of these subgroups are shown in Table II.

5.2 Amniotic fluid embolism (25 cases)

This process is clearly far more common than is appreciated in the obstetric literature.49 The hypervascularity of the uterus and other pelvic structures in pregnancy and the considerable pressures that labor can generate make such a risk one easily understood a priori. However, two fatal cases occurred in women who were not in labor at all.

It should be noted that some significant distinctions exist in time between infusion of amniotic fluid into the maternal circulation, the onset of clinically observed or significant symptoms, and the time of death thereafter. No strict pattern of manifestation is seen, but several typical expressions of the disorder are seen.

A profile of the woman with amniotic fluid embolism/infusion follows: She is usually 25 years of age or older, in her third, fourth, or fifth pregnancy; and is at or very near to term (37 to 41 weeks' menstrual age). She is more likely not to have sustained a prior fetal loss or miscarriage. This combination of age and parity is occasionally replaced by a young primigravida with precipitate labor or tetanic contractions. Although about 8% of cases occur before labor begins, vigorous labor is the rule. This can be spontaneous or related to use of uterine stimulants. In fact, almost half occur during or after oxytocin/tocosamine overdose. The second most important factor is a tear somewhere in the birth canal, affording access for amniotic fluid into

the maternal venous system. Fetal malpresentation contributes to amniotic fluid infusion. For example, in one patient a hydrocephalic fetus could not enter the pelvis during labor.

The herald of the infusion is usually sudden and may be clinically silent, with later onset of disseminated intravascular coagulation as the first clear sign. The sign can be apnea, the appearance of embolism in the chest, tachycardia, or sudden onset of fever. In several instances a seizure was the first sign, attributed to pulmonary insufficiency and acute hypoxia from massive lung embolization.

The onset is concentrated about the immediate perinatal time frame, in particular from about 1 hour before delivery to 30 minutes afterward. The final few minutes of labor carry as much risk as the immediate postnatal few minutes. The sudden changes in intrapelvic pressure and blood flow that occur with fetal passage seem to enhance amniotic fluid infusion.

The embolization can be so massive that survival thereafter is measured in minutes. Eight of 25 women died in the first 6 hours postpartum, and 72% died on the first day. This concentration of survival weakens attribution of late deaths to amniotic fluid embolization. In later deaths the intermediate steps of disseminated intravascular coagulation and hemorrhage must be documented. A unique case showing both amniotic fluid embolism and delayed pulmonary thromboembolism is presented below in abstract form.

The pulmonary lesions of amniotic fluid embolization consist of amniotic fluid bubbles and transported fetal squamous cells regularly found in amniotic fluid, which are commonly seen in air spaces of fetal or neo1134 Shanklin et al. October 1991
Am J Obstet Gynecol

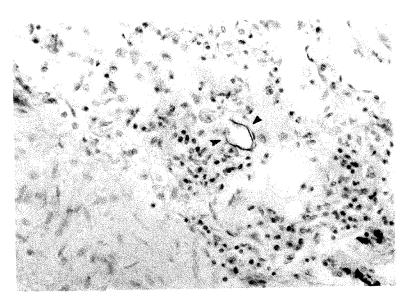

Fig. 3. Amniotic fluid embolization. Nonstaining intravascular bubble of amniotic fluid demarcated by surface-adherent embolic fetal squamous cells (arrows). The photograph is necessarily limited to a single focal plane; focusing up and down over such foci confirms the molded spheroidal form expected from a fluid bubble or droplet with a surface tension interface within lung vessels. Air or nitrogen embolism has a similar appearance. (Hematoxylin and eosin; original magnification $\times 250$.)

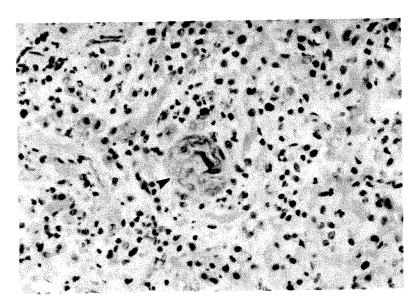

Fig. 4. Amniotic fluid embolization. Retained and intact clump of embolic squamous cells within a field of subacute pneumonia. Thirty-three-year-old gravida 3, para 2, dying 22 days postpartum. Multiple foci of embolic squames and some lanugo hair were also present. (Hematoxylin and eosin; original magnification $\times 250$.)

natal lungs after various late pregnancy stresses. These cells are easier to find (Fig. 2), but bubbles can be identified as spheroidal fluid-filled spaces within lung capillaries, venules, and arterioles. Their shape can be confirmed by skillful focusing at multiple planes during microscopic examination. Occasionally one is rewarded by finding squames and bubbles together (Fig. 3). The

embolic squames are resistant to digestion, even when pneumonitic exudate is present (Fig. 4). Their persistence is helpful in recognizing amniotic fluid embolization beyond the more common time period for this disorder (see Miniabstract 1, Section 5.2.1).

Glomerular lesions are important in the assessment of amniotic fluid embolism or subsequent disseminated

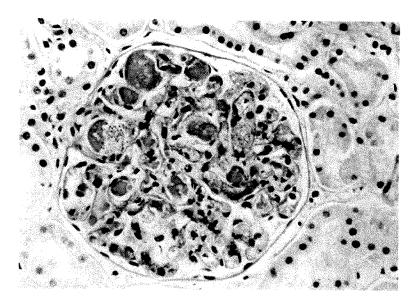

Fig. 5. Amniotic fluid embolism; disseminated intravascular coagulation. Multisegmental glomerular thrombosis in left kidney. Some granular formalin pigment is present. Tumultuous labor in a 45year-old gravida 6, para 5; death 7 hours postpartum. Right kidney had been removed 13 years earlier for hypernephroma. Left kidney also contained a small angiolipoma. (Hematoxylin and eosin; original magnification $\times 250$.)

intravascular coagulation. Fig. 5 shows multiple lobular thrombi within capillaries of the glomerular tufts. The working party did not find squames secondarily transported to glomeruli. This theoretic possibility might occur because of intrapulmonary vascular shunts after segmental obstruction. By contrast, fluid bubbles were seen in a few cases and should be sought in all deaths close in time to the ictal event.

Amniotic fluid infusion is a significant cause of perinatal death as well. In this series two fetuses died with the mother, six were stillborn, and one died 2 hours postnatally. This perinatal mortality rate of 36.3% is essentially the same as the overall rate of the 20-year series (Table I), with a closely similar distribution between stillbirth and neonatal death.

5.2.1Miniabstract 1

A 22-year-old woman, gravida 3, para 1, abortus 1, had her first pregnancy at term 2 years earlier, with a birth weight of 3200 gm. In the forty-first week labor was augmented by 5 IU oxytocin/500 ml in 5% dextrose in water at an unknown rate. Labor was noted to be vigorous and almost continuous. Artificial rupture of the membranes (AROM) occurred just before delivery of a 3600 gm surviving newborn. Two hours postpartum, there was a sudden onset of marked bleeding. Two units of O- and two units B-type specific blood were given. A hysterectomy was performed 5 hours postpartum. On the eighth day massive pulmonary thromboembolism (PTE) occurred, and the patient died. Autopsy showed renal cortical necrosis and nonorganizing recent thrombi in ovarian and renal veins and the inferior vena cava. Microscopically, widespread AFE was also found.

Comment: This combination of AFE and PTE is rare. In fact, this was the only proven case in the entire series

of more than 1100 cases. A direct pathogenetic relationship is unclear. A factor to be considered is that excellent, prompt surgical and general medical response to the early amniotic fluid embolization allowed survival into the risk period for thromboembolism of the ordinary puerperal sort. The possibility of a rebound of coagulation factors into a hypercoagulable state cannot be excluded, albeit in this case daily determinations of the ordinarily studied factors were not done.

5.2.2 Miniabstract 2

A 44-year-old woman, gravida 2, para 1, was scheduled at term for repeat section because of a deformed pelvis presumably caused by poliomyelitis. Current pelvic evaluation suggested no pelvic deformity of obstetric significance. Her weight fluctuated in the late third trimester, from 70 up to 75 and then down to 69.6 kg. In early labor she was given pentobarbital, 100 mg, at 7:55 PM; meperidine, 75 mg, and atropine, 0.4 mg, were administered at 8:05 PM. She developed persistent emesis. with episodes at 8:30 PM and 8:45 PM, bore down at 8:50 PM, and became cyanotic at 8:51 PM. An immediate moribund section was done. The mother died 20 minutes postpartum. The 3629 gm slowly responsive infant died at 14 hours. Autopsy on the mother revealed pulmonary amniotic fluid embolism and a large crumpled sheet of amniotic membranes within the right pulmonary artery.

Comment: Pathologists with experience in posttraumatic injuries look for embolism of tissues such as bone marrow, splenic pulp, and brain. This is merely the pregnancy extension of this general principle: bulk deportation of tissue fragments. The ready deformability of the membranous amniochorion might more often

Table III. Maternal deaths from gestosis ("toxemia")-related conditions

Thiazide misadventure	1	0.356
GROUP TOTAL	24	8.54

yield this obstetric disaster were it not for the limited size range of the inner uterine venous sinuses in late labor and early puerperium.

These two cases illustrate extremes in the lesional potential of embolism of amniotic content, one hidden from clinical and pathologic view except through the possibly connected sequel of pulmonary thromboembolism, and the other a mass transport of portions of the reflected membranes. Although uncommon, both require autopsy to confirm or rule out. The rule of thumb would be that massive embolism is fatal or severely distressing very close to delivery; lesser degrees manifest later; and as suggested by the first case, death or severe distress may occur in the time frame more likley attributed to thromboembolism not derived from the effects of amniotic fluid infusion.

5.3 Ectopic pregnancy (9 cases)

On a priori grounds abdominal ectopic pregnancy would more likely manifest in later pregnancy. The one case represented here is a partial exception, with death occurring at an estimated 14 to 16 weeks' menstrual age. Nevertheless, such a view is confirmed by this small series, although at an interval much less than with some reported abdominal pregnancies. The other eight cases had a range of gestational age of 5 to 11 weeks; two were themselves only estimated ranges from reconstructed menstrual histories, 8 to 10 and 8 to 11 weeks, respectively.

The pathologic findings are those of disruptive hemorrhage in the uterine tube or cornu with or without extrusion of the conceptual sac. The implantation may be on the opposite side of the adnexae from the corpus luteum of pregnancy. The problems of interpretation of signs and symptoms of ectopic pregnancy can be mitigated by approaching all examples of early pregnancy distress as potentially those from ectopic implantation.

5.3.1 Miniabstract 3

The patient was 35 years old. Her parity was unrecorded. She had severe pelvic pain at first with eventual physical col-

lapse. Multiple telephone calls were made to physicians to attend her at home without success, and she steadfastly refused to report to an emergency room (ER) or to be taken there by her husband for 6 hours. She apparently became unconscious about 3 hours before actually visiting an ER at 11:55 pm. Fifteen minutes after arrival at the ER she went into cardiac arrest; vigorous resuscitation for 40 minutes was unsuccessful. Autopsy revealed a very obese woman, greater than 111 kg (250 pounds) and 162 cm (64 inches) tall. A ruptured tubal ectopic site at an estimated 5 weeks' gestational age was found. About 1500 ml of blood filled the abdomen. An unruptured 900 gm simple serous cyst of the right ovary was also present.

5.3.2 Miniabstract 4

A 26-year-old woman, most likley a primigravida, came to the United States as a military bride. She spoke no English. Her soldier husband was on extended duty in the country of her origin. She lived with a man calling himself an "uncle" but who was apparently from the same military unit. He did not speak her language. There were two visits to an ER during the evening for vague discomfort. She was accompanied by this man. There were indications she experienced overt abdominal pain at about 5:30 AM. On the third ER visit 3 hours later (the "uncle" brought her in), she was dead on arrival. Autopsy revealed ruptured tubal ectopic pregnancy and massive abdominal hemorrhage.

Comment: The rapidity of progression of hemorrhage from pelvic vessels dilated by the hormonal effects of pregnancy is impressive. The pathophysiologic conditions do not allow for ceremony in obtaining or giving appropriate obstetric care. Rapid serum and urine tests for chorionic gonadotropin are generally available and highly sensitive. Thus a rupturing tubal gestation should be susceptible to diagnosis. A completed tubal abortion is, fortunately, not usually associated with the type of bleeding ordinarily seen in rupturing ectopic pregnancies. Lest one conclude that the risk for maternal death from ectopic pregnancy is diminishing, one of the nine cases is from the next to last year of this survey (1984).

5.4 Gestosis ("toxemia of pregnancy") (24 cases) This pathophysiologic syndrome continues to be of great clinical significance with the same broad range of

lesions and functional effects that the more classic reports so well delineated.^{15, 28, 54} Table III reflects the overall principal types and our assignment of these to major categories. Several other cases in which some evidence suggested the presence of or the early onset of gestosis were found, but on further analysis this was considered of minor importance in the mortal outcome. Given the occasional cases of puerperal eclampsia without apparent prior warning and reassignment of maternal deaths to gestosis after careful autopsy examination, the possibility of a subtle but nonetheless important factor cannot be readily dismissed. As an example of this, attention is here drawn to the discussion on the relationship between pregnancy and intracranial arterial aneurysms (Section 7.5).

The two dozen mothers with fatal gestosis showed considerable variation in age, gravidity, parity, and gestational age at time of delivery. A few general statements can be made.

5.4.1 Age range

The ages ranged from 15 to 42 years. The mean was 28.4 years, with 28.5 years as the effective median. Although the younger women had generally lower parity as expected, there was one primigravida at age 34 years; the highest gravidity in the younger women was 3 at age 25 years. The age spread is fairly uniform. In fact, the largest cluster is a quarter of the cases at ages 33 to 35 years.

5.4.2 Gravidity-parity

By contrast, gravidity-parity status was less uniform. Contrary to the still common misconception of gestosis as a disorder of first pregnancy, fatal gestosis in primigravidas accounted for only 11 of these 24 women (45.8%). There were five secundigravidas, four at gravida 3, two at gravida 5, and one each at gravida 8 and 9. The average gravidity was 2.5, but the average parity was a low 1.17. The difference was accounted for by both spontaneous miscarriages and pregnancy terminations. The highest parity was 6.

5.4.3 Gestational age

Gestational age at time of delivery seemed to reflect the well-known tendency toward premature onset of labor. Twelve deaths occurred at or near term (38 to 42 weeks inclusive), half the total. The remainder spanned 24 to 37 weeks, with one quarter of the cases clustered at 321/2 to 35 weeks. However, this aspect of gestosis as a factor in maternal death must be examined in the light of the high section/hysterotomy rate, 10 of 24 (41.7%). Seven sections were done before onset of labor and an eighth was done in very early labor when no progress in station or dilation had been observed. These account for 6 of the 12 "preterm" deliveries; 2 were because the mothers died undelivered at 321/2 and 34 weeks. Thus in this experience, early delivery of the fetus was largely, if not wholly, a consequence of obstetric intervention for abruption; eclamptic seizures; or severe, progressive gestosis.

5.4.4 Perinatal mortality

The perinatal mortality is of interest. The rate of fetuses dying undelivered with the mother was half that of the overall series, 2 of 24, 8.3% (against 40 of 281 [17.1%]; see Table I). The stillbirth rate was three quarters that of the whole series, 4 of 22, 18.2% (against 52of 217 [23.6%]), and the neonatal death rate was 2 of 22 (9.1%), essentially the same as the overall rate of 8.7% (Table I). Sections were productive of one stillborn and two neonatal deaths, the former a relatively low figure and the latter relatively high. They are connected in that prompt section to salvage the infant or to interrupt the gestotic process will deliver a number of fetuses already so badly stressed that they do not survive postnatally. The overall survival rate for newborns is a mildly enhanced 72.7% against the overall datum for the series of 66.8% (Table I), but section did not contribute to this improvement. One was delivered at 30 weeks from a primigravida aged 21 years with a prior history of childhood nephritis, a blood pressure surge to 290/180, and three seizures during the confinement. The infant was small for gestational age, had a 1-minute Apgar score of 2, and lived almost a day. The second postsection neonatal death was from a 24year-old primigravida at 241/2 weeks' gestation. There was fulminant eclampsia with a blood pressure surge to 220/120, several seizures, and massive cerebral hemorrhage 3 hours postpartum. The infant weighed about 600 gm and lived almost a day. The sole stillbirth by section is similar. This was a 32-year-old woman, gravida 3, para 2, in the twenty-seventh week of pregnancy. Prenatal care had just begun but was a caloric restrictive, low-sodium regimen. She was in an early obtunded state, and hysterotomy was done for fetal death to interrupt the gestotic process. She survived this by 51 hours; autopsy showed classic eclamptic changes in kidney and brain.

Thus section cannot be independently faulted because all three mothers had fairly severe early gestosis, but because the only two neonatal deaths among gestotic women were section delivered, a positive contribution of section to neonatal outcome is marginal at best and more likely irrelevant. From this experience, it would seem that abdominal section should be done on women with progressive gestosis for obstetric but not for fetal indications.

5.4.5 Pathologic findings

Gestosis, or eclamptogenic toxemia of pregnancy, is a pathophysiologic state with moderately varied pathologic organ findings. Two visceral lesions are especially associated. The first is in the renal glomerulus (Fig. 6) and is essentially a capillary endotheliosis with a more varied mesangial component.29 The second is liver dam-

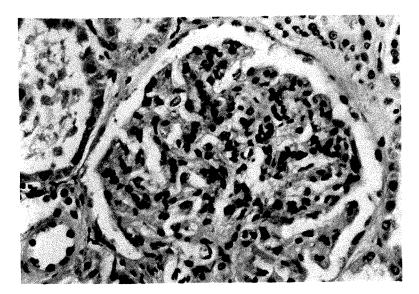

Fig. 6. Glomerulus in severe preeclamptic gestosis; 17-year-old primigravida. Lesion at this power of resolution by light microscopy appears as moderate hypercellularity, some of which is endothelial and some mesangial. Ruptured subcapsular liver hematoma and peritoneal exsanguination were found at autopsy. (Hematoxylin and eosin; original magnification \times 250.)

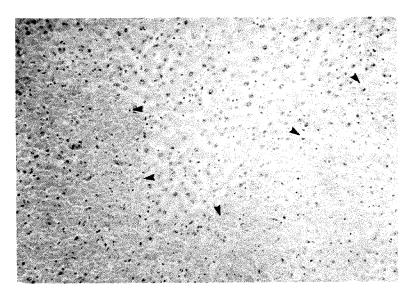

Fig. 7. Liver in severe eclamptic gestosis. Confluent necrosis on three sides of remnant liver tissue showing nutritional atrophy, loss of glycogen. This necrosis is more advanced than that in Fig. 8. Arrows denote a fairly sharp line of demarcation between the necrotic and viable zones. Depending on the degree of added heart failure, sinusoidal congestion will become hemorrhage in the zones of necrosis. (Hematoxylin and eosin; original magnification $\times 100$.)

age. In its most extreme form this is a confluent periportal-to-midzonal necrosis (the change representing extension of the process) (Figs. 7 and 8). The intermediate lesions are less well known. This is most likely because kidney biopsy has been done much more often than has biopsy of the liver. ^{26, 29} More recent findings still under investigation are uterine boundary zone endothelial changes and injury. ⁴⁸

The earliest cardiovascular pathophysiologic change is blood volume restriction, but after renal sodium retention mechanisms have been invoked,³⁸ congestive heart failure may be superimposed with added injury to the liver. In fact, underlying hepatic dysfunction may be found, possibly derived from protein deficiency.^{19, 46} This is reflected in liver cell changes short of necrosis that then lead to cell death and tissue necrosis with the addition of heart failure. Systemic mitochondrial injury

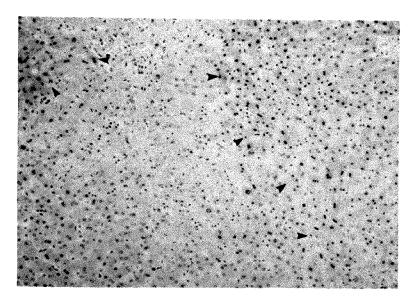

Fig. 8. Liver in severe eclamptic gestosis. Two zones (arrows) of preinfarctive pyknotic cellular changes in midzone of liver lobule. In some cases these changes are even more discrete. State of lesion at autopsy depends in part on the interval of survival and duration and depth of postictal shock. (Hematoxylin and eosin; original magnification $\times 100$.)

Osteogenesis imperfecta	Í	
Postoxytocin	1	

is a likely factor here. 48 Blood liver enzyme values rise as one feature of a severe variant of gestosis, the HELLP syndrome (hemolysis, elevated liver enzymes, low platelets), which has resulted in maternal death. 10 The total bilirubin in the cited case report was 4.5 mg/dl, a finding supportive of liver cell injury. Another point in favor of this is a high frequency of diffuse sinusoidal congestion in livers as seen by the working party in review. This in turn relates to capsular hematomas and intraperitoneal rupture and hemorrhage. Because the terminal mechanisms are those of acute hypovolemic anemia, little blood is present to pool passively in the liver sinsuses as part of the agonal events. It more likely that this occasional finding is the remnant of an earlier sequestration from adaptive hemometakinesis compounded by right heart failure.

Table III shows that three maternal deaths were the result of severe liver injury. Acute fatty liver is an advanced metabolic injury^{30, 36} with further consequences of hepatomegaly and interference with protein synthesis including clotting factors. The relation of this to microvesicular fatty change⁷ is currently under study. Although the renal lesions have been better studied, in cases of gestosis in which fatty liver dominates, the lethal lesions are in the brain and not the kidney. Superimposed acute tubular necrosis is unusual.28 Clinical renal shutdown from failing prerenal circulation is more common; if renal failure is deep but transiently relieved, the more advanced lesion may be found later at autopsy.

Depending on treatment modality, lung injury in the form of adult respiratory distress syndrome may be superadded to this list. Diffuse edema of the cerebral neuropil is often found to supplement the glomerular and hepatic changes of gestosis. This does not preclude the occurrence of overt space-occupying intracranial hemorrhage. In some instances hemorrhage is just the effect of rapidly progressive hypertension on a congenital aneurysm. Medial defect aneurysms of the major intracranial arteries are fairly common in women of childbearing age.24,25 Mass hematomas in the lenticulostriate region of the internal capsule are often so destructive of tissue that an underlying aneurysm cannot be identified. The extent of some of the hematomas is shown by one filling the third and both lateral ventricles with extensive subarachnoid hemorrhage. Such hematomas should not preclude close study of the kidney and liver to ascertain whether the underlying disorder is that of gestosis.

Of the lesser associated lesions, the one case of myocardial infarction is especially instructive. This woman had typical moderately severe gestosis without seizures. She was a 23-year-old primigravida with a strong family history of hypercholesterolemia. The blood pressure surged to 200/110 during labor. The delivery was by midforceps using local and nitrous oxide anesthesia. The 2722 gm infant lived. On the eighteenth puerperal day the episiotomy broke down and a secondary repair was necesary. Five days later she died suddenly at home. Autopsy revealed severe coronary arteriosclerosis; occlusion of the left anterior descending coronary artery; diffuse necrosis of an enlarged left ventricle; and diffuse, severe pulmonary edema.

Therapeutic misadventures add to the underlying burden of gestosis. In one magnesium sulfate and hypotensive agent overdose (10 ml, 50% intravenous magnesium sulfate plus 10 ml reserpine [2.5 mg/ml]) was compounded by the use of spinal anesthesia in an obese woman with small stature and short neck (weight, 102 kg; height, 152 cm or 59.8 inches). She died 5½ hours postpartum. An intense 5-week use of thiazides in another patient greatly constricted the blood volume, leading to hypovolemic anemia and hypotension. The pancreas was not examined at autopsy for evidence of thiazide effects.^{4,11}

5.4.6 Miniabstract 5

The patient, a 21-year-old gravida 1, had a small gynecoid pelvis, and was 148.6 cm (58.5 inches) tall. At 9 years of age she was diagnosed as having "nephritis." A questionable past history of epilepsy existed. Her blood pressure rose during pregnancy from 120/86 to 240/160; the urine albumin increased to 4⁺. In the thirtieth week of gestation she complained of headache, was admitted, and her pressure surged to 290/180. There were three seizures. She collapsed and became apneic. Section delivery produced an unweighed "small" newborn with an Apgar score of 2, who died later the same day. The mother died 24 hours after delivery. Autopsy revealed typical gestotic glomerular lesions and no evidence of prior neprhitis. Multilobular he-

patic necroses and numerous intravascular fibrin deposits were found throughout the brain.

Comment: This case was also briefly noted above. It is presented here in greater detail to illustrate that occasionally the clinical history of predisposing renal disease is not confirmed by autopsy study. The childhood records were not available to the committee nor to the working party, but cogent autopsy examination of the kidneys ruled out any remnant or contributory lesion of the kind usually designated as nephritis.

5.4.7 Miniabstract 6

A 34-year-old woman, gravida 2, para 1, delivered in the thirty-third week of pregnancy. The first pregnancy was unremarkable. Her blood pressure rose in early third trimester to 180/108 and then spiked to 190/120 with onset of abdominal pain and headache the day before section delivery. She was treated by three intramuscular doses of magnesium sulfate, 2 gm each in rapid succession, and was then sent to a second hospital with a diagnosis of "sepsis." On arrival there she was obtunded, apparently having sustained a seizure en route. Hydralazine hydrochloride, 20 mg, and more magnesium sulfate, 4 gm, were given rapidly by vein. Shortly thereafter she went into respiratory arrest, and calcium gluconate was given with effective results. Respirations remained spontaneous. Section at this point produced a surviving newborn weighing 1590 gm. The mother continued to have both cerebral and lung difficulties, was treated with barbiturate suppression, and died on the eleventh puerperal day. Autopsy showed typical renal lesions of gestosis, a massive left intraventricular cerebral hemorrhage, and another smaller one in the right basal ganglia. No evidence of sepsis was found.

Comment: This was not coded as a magnesium sulfate misadventure because of (1) the prompt recovery after calcium injection, (2) the massive intracranial hemorrhaging, and (3) the delayed puerperal death. To be considered a magnesium sulfate death, the sequence would have to be closer in time and more direct in process despite the loading doses over a short time period.

5.4.8 Miniabstract 7

The patient was a 41-year-old gravida 6, para 5, at term. All prior pregnancies were uneventful. Her blood pressure had been elevated for 3 weeks and peaked at 200/130. She had marked foot edema and 4⁺ albuminuria. Three days before delivery she was in an automobile accident but had no major injuries; "bumped about" best describes her condition. Labor ensued and was augmented by six doses of oxytocin intramuscularly, 2 minims each. She had a seizure and lapsed into a coma. A Vorhees bag was unsuccessful; version was begun but the cord prolapsed as the mother went into a coma. Nitrousoxygen-ether anesthesia was also administered. During preparation for section she was maintained only by those resuscitative efforts available in the early 1950s for about an hour. The section was either in the late agonal period or after death, and the fetus was beyond resuscitation. This fetus was coded by the working party as dying with the mother. No autopsy was performed so that the possible role of the motor vehicle accident

remains unclear. Neither marrow nor amniotic content embolization can be ruled out from available data.

Comment: This case shows the complexity added both to pathogenesis and the analytic process by late pregnancy physical trauma. Consider the possibilities if a woman with progressive gestosis becomes medically disabled while driving, leading to a vehicular accident.

Extracranial nongestotic hemorrhage (14

This category includes those hemorrhages arising from pathophysiologic changes specifically related to the reproductive tract but in the absence of gestosis or toxemic manifestations and in the absence of amniotic fluid embolism (Table IV). Three basic lesions occur in this group: (1) uterine atony, (2) tears in the reproductive tract, and (3) placental abnormalities. There was only one case of uterine atony, a 25-year-old, gravida 3, para 0, who delivered at home. She began to bleed heavily, was taken to a hospital, and the placenta was delivered in the ER. Irreversible brain damage from exsanguination had already occurred. She died after a coma lasting 4 days.

Lacerations in the birth canal occur frequently but are not often directly lethal. The extreme form of this is a ruptured uterus. This occurred once after oxytocin without superimposed amniotic fluid embolism. The ruptured uterus in a woman with osteogenesis imperfecta is of interest. The mother was a 30-year-old, gravida 2, para 2, who sustained lacerations of the cervix and vaginal vault in her first pregnancy. The second labor was uneventful. Her third labor was characterized by intense contractions especially in the latter half of the first stage, a pattern observed in both prior deliveries. Mild premature separation of the placenta was present; the infant was liveborn, weighed 2800 gm at 38 weeks, and died of hyaline membrane disease. The infant also showed osteogenesis imperfecta. The mother had religious objections to blood transfusions. Fluorocarbonic acid blood substitutes were tried without success; she died 5 hours postpartum.

The placental lesions are those commonly considered to have grave risk for heavy bleeding ab initio, placenta previa accreta, and abruptio placenta. Two of the abruptions triggered the sequence of disseminated intravascular coagulation. One occurred at 26 weeks gestation in a patient with mild gestosis and Rh sensitization. An exchange transfusion was planned, but she was admitted with backache and bleeding that progressed to abruption and Couvelaire uterus. Supracervical hysterectomy was used to control bleeding, and nearly 13,000 ml of intravenous fluids were infused over a 4-day period leading to pulmonary edema. The final patient with abruption, a 31-year-old, gravida 5, para 4, had a ruptured uterus without specific obstetric antecedents. The lacerations went deeply into the adnexal tissues.

5.5.1Miniabstract 8

A 27-year-old woman, gravida 3, para 2, had both prior deliveries by section. She was in the twenty-fourth week of pregnancy with proven marginal placenta previa and early signs of bleeding. Oxytocin induction was begun and delivery was by low forceps. The 822 gm infant lived less than 2 hours. Hemorrhage after delivery was controlled in part by supracervical hysterectomy. Recognition of a cervical laceration led to subsequent excision of the cervix. The surgical specimens revealed partial placenta accreta. Hypovolemic shock intervened and became irreversible with death 5 hours and 10 minutes after delivery.

Comment: This case is a particularly compelling combination of obstetric problems. Marginal placenta previa beginning to bleed in the twenty-fourth week of gestation portends a poor prognosis for the fetus. One might wonder why, in the face of two prior sections. a hysterotomy was not done to relieve the situation. On the other hand, considering the large number of births represented by this 20 year review, this is the only case directly connected to placenta previa as the principal pathophysiologic factor. This might seem like a salutary state of affairs. A commonly noted frequency of placenta previa, however, is about 1 in 300.37 Thus one of 281 maternal deaths is not a significant difference from the expected range. Some authors have given a higher rate for previa, 1 in 168,34 and 1 in 281 is more likely a real difference compared with that baseline.

5.5.2 Miniabstract 9

A 40-year-old woman, gravida 8, para 2, abortus 2, was in the fortieth week of pregnancy. There had been prior cervical surgery; the record was unclear whether this was a conization or a partial amputation. Labor augmentation consisted of 5 IU oxytocin in 500 ml of normal saline solution given over 1 hour. Delivery was an assisted breech extraction with Piper forceps on the aftercoming head. The placenta was removed manually: a lacerated lower uterine segment and cervix and a ruptured uterus were found. Hysterectomy was performed 3 hours postpartum. Death occurred 5 hours after birth and 2 hours postoperatively. Hypovolemic shock was irreversible despite surgical removal of the lacerated uterus. The 2892 gm infant survived.

Comment: There was no evidence of amniotic fluid embolism despite the close match of the case to the profile of higher risk for amniotic infusion and the excessive use of oxytocin.

The normal variations in anatomic arrangements of human placentation and the normal adaptations of the reproductive tract in labor carry an inherent risk of hemorrhage. This risk would be diminished by avoidance of excessive force in labor management. Abruption other than that in preeclampsia may be an apparently random event with some relationship to higher parity, just as previa seems to be.37 Three of these four

1142 Shanklin et al.

October 1991
Am J Obstet Gynecol

patients were para 4 or more in the index pregnancy. Atony is also more likely in the multiparous uterus. The relationship of osteogenesis imperfecta to tears in the birth canal remains problematic because only one case occurred, but the repetitive nature of the lesions opens the matter to speculation. It may be that a more general mesenchymal disorder is present in some individuals, such that the soft tissues of the canal tear more readily.

5.6 Obstetric neoplasmas (6 cases)

Neoplasms of the placenta represent the only true obstetric tumors. Theoretically the placental hemangioma, or chorangioma, could lead to maternal death through the mechanism of abruption or retention as a placental polyp. Chorangiomas large enough to be seen with the unaided eye would qualify, but these occur in only about 1 in 1200 pregnancies,44,45 and such sequelae are rare. The working party found no example of this phenomenon in more than 1100 maternal deaths between 1949 and 1985. Neoplasms of the placental site trophoblast would also be an unusual form of obstetric maternal death,18,45 but none were found on review by the committee during this 36-year period. The more expected trophoblastic tumors did occur. There were five cases of choriocarcinoma, all from the first half of the 20-year period specially emphasized in this report, and one example of fatal chorioma, grade 1 (chorionic molar pregnancy). Five cases are insufficient for a profile analysis, but some interesting aspects are remarkable.

Two women were in their first pregnancy, ages 23 and 21 years, respectively. One was diagnosed at 12 weeks as having chorioma, which was evacuated and interpreted as grade 1. Six months later the human chorionic gonadotropin titer was zero, but soon thereafter an explosive metastatic spread of choriocarcinoma was recognized and she died before the end of the year. The second primigravida went to term and delivered a healthy child. Eleven months later she was diagnosed as having metastatic choriocarcinoma and lived less than a month thereafter. The survival for both cases of primigravidous choriocarcinoma patients was less than 1 year.

The third patient was a 27-year-old, gravida 4, para 4. On the third puerperal day hemoptysis occurred, which was attributed to pulmonary tuberculosis. Eventually the correct diagnosis of metastatic choriocarcinoma was established; she died on the one hundred thirty-third puerperal day.

The remaining two patients were of high parity. One was 40 years old, gravida 9, para 8. Eight years earlier curettage removed a grade 2 chorioma; 2 months after diagnosis hysterectomy was done. Approximately 1 year before death intraabdominal hemorrhage occurred and was caused by metastatic liver lesions. Chemotherapy was applied generally and into the hepatic

artery to no avail. The other was a 52-year-old woman, gravida 10, para 9. At age 47 years a grade 1 chorioma was removed by evacuation. Recurrences were at 2 and 3½ years later; the first was treated by hysterectomy and the second by local vaginal excision. At 18 months further metastatic lesions were discovered in the brain. She died soon thereafter.

5.6.1 Miniabstract 10

The patient was a 24-year-old primigravida with an initial prenatal visit in the ninth week of pregnancy. She was of average stature and in apparent good health. Shortly thereafter two episodes of vaginal spotting occurred and in the eleventh week the fundus was palpated at 8 cm suprapubic. Hospitalization for diagnosis and treatment followed. She died suddenly 5 days later. Autopsy revealed a locally invasive chorioma with Clostridium sepsis, disseminated intravascular coagulation, and widespread gas embolization.

Comment: There was no reason from the available clinical information to suspect illicit or unreported instrumentation of the uterus, the case occurred in the early 1970s. Instrumentation is not a necessary part of pathogenesis because local injury to the bowel wall from pelvic spread of invasive chorioma is a sufficient portal of entry for clostridial species normally found in the colonic flora. Neither the clinical studies, for which there was little time, nor the autopsy addressed the question of specific immune deficits or possibilities such as familial neutropenia, which predispose to clostridial infections once outer barriers are breached.

5.7 Therapeutic misadventure (7 cases)

One case was classified here rather than under anesthetic misadventure because the committee was unable to learn what anesthetic agent was used. Direct attribution was, accordingly, not possible. The case in question was that of a 20-year-old primigravida in the fifteenth week admitted for termination of pregnancy by dilation and curettage; cardiac arrest occurred during the preliminary examination under anesthesia (EUA). The woman never regained consciousness.

The other cases in this group included three additional pregnancy terminations, all by saline solution injection into the amniotic sac. Two were very similar. One patient was known to have lupus erythematosus at age 21 years and in the first pregnancy at 19 weeks. She lapsed into stupor 4 hours after receiving 165 ml of 20% saline intraamniotically. The second was 23 years old, of unknown parity, at 22 weeks. The procedure was begun in another state. She was transferred obtunded and died soon after admission. The third death after saline injection was also 23 years old, gravida 3, para 2. This procedure was also begun out of state. On admission partial delivery of the presenting breech was found. The placenta was 75% separated, and the patient died from exsanguination.

The remaining three cases are of interest for the range of possible problems in pregnancy perhaps not

always considered as sources of difficulty. The first was a 36-year-old woman, gravida 4, para 0, with three prior spontaneous abortions. A class 4 smear and extensive Schiller negativity on the cervix prompted admission for conization. Submucous injection of 1 ml of 1:1000 epinephrine with 9 ml of saline (not local anesthetic) was followed by almost immediate apnea. Resuscitation was unsuccessful, and she was declared dead 47 minutes later. Cervical tissue revealed probable early invasion by epidermoid carcinoma. Bolus injection into the hypervascular cervix of pregnancy seems the most likely mechanism of what was an overdose even in the most aggressive treatment plan and very much so with the intended vasoconstrictive effect for local anesthesia.

The second was a possible idiosyncratic reaction to methylergonovine maleate. The patient was 26 years old, gravida 3, para 2. No antecedent obstetric abnormality or positive family history was found. Both prior deliveries were uneventful. Labor and delivery were normal. Eight minutes after birth of the surviving 2860 gm infant, intramuscular methylergonovine, 0.2 mg (the normal dose), was given for third-stage uterine contraction. In a "few minutes" she developed headache, after which her blood pressure rose to 180/110, and 3 hours postpartum a grand mal seizure occurred. She lapsed into a coma and died 4 days and 111/2 hours later. Careful examination of the brain revealed no aneurysms but a 100 ml blood clot in the right lateral ventricle. There were no heart lesions. Neither renal nor hepatic lesions of gestosis were present. As in the case noted directly above, the possibility of direct intravascular injection cannot be excluded.

The final case in this group involves lapse of medication effects. A 19-year-old woman with a strong family history of epilepsy was diagnosed as being epileptic 2 years before her third confinement. Delivery was spontaneous after spinal anesthesia. The first delivery was at age 16 years; the second delivery was at 17 years of age after a diagnosis of gonorrhea during pregnancy. She had been maintained on phenytoin sodium, 300 mg three times daily; immediately postpartum this was reduced to 100 mg three times daily; patient compliance was not documented. She died in status epilepticus on the eighth puerperal day. Postmortem study revealed no phenytoin in the blood. No other likely medication was found either. The autopsy was otherwise unrevealing.

6.0 Pregnancy: A probable major contributory factor 6.1 General

In this major section, the fact of pregnancy is considered to be contributory, whereas the mortal pathogenetic factors are not pregnancy exclusive. This situation will be seen especially in Section 6.3, anesthetic misadventure, and in Section 6.5, pulmonary thromboembolism. Inclusion of puerperal sepsis here is possibly debatable, yet the working party noted an even

larger group of infectious illnesses that did not have the reproductive tract as their portal of entry. Those cases are in the third group (Section 7.0). A case might be made for placement of this group in Section 5.0 were it not that acute bacterial endometritis leading to parametritis sometimes occurs without pregnancy. Moreover, not all puerperal uterine cavities become infected, although the lower birth canal cannot be effectively sterilized for birthing. Thus although pregnancy is a major factor in these cases, it is not a unique one, which was the criterion for the general classification as noted in Section 5.1.

Overall, 54 pregnant or puerperal women died with these findings. This is 19.2% of the series grand total of 281 cases.

6.2 Air embolism, post coital (1 case)

The patient was a 22-year-old primigravida in approximately the twenty-eighth week of gestation. So far as known (and the autopsy did not reveal otherwise) the prenatal course to that time was normal. She collapsed during heterosexual intercourse. She was dead on arrival at a nearby hospital. Autopsy revealed 30% placental separation. There was foamy froth in the right atrium and the right ventricle of the heart, which was otherwise normal. The lungs were wet, weighing 1300 gm together (about three times normal for her age); amniotic fluid embolism was absent. The uterine cavity contained a liter of admixed blood and amniotic fluid. There was no lesion in the brain.

This pathogenetic mechanism, although rare, is not unique.5

6.3 Anesthetic misadventure (13 cases)

These patients are delineated in Table V. The first case might have been included in the group of therapeutic misadventures noted above in Section 5.7 but was assigned here by the working party because of failure of the patient to recover from anesthesia without overt signs of specific intraanesthetic events, such as cardiac arrest during an EUA. In this case, some of the anesthetic and analgesic agents were known.

The principal anesthetic problems during obstetric procedures are those of anesthesia for surgery in general. There were five cases of pulmonary aspiration; two were so massive they caused immediate ventilatory obstruction with eventual death from combinations of pneumonia and cerebral hypoxic injury. Lesser degrees of pulmonary aspiration are followed by pneumonia (from the foreign material inhaled, including gastric secretion), which often produces inexorable destructive inflammation. There were two such patients both surviving 2 weeks. Problems with anesthetic agents such as multiple serial anesthetics, failed spinal anesthesics, and spinal overdoses ("high spinal") make up a good share of these cases (5 of 13), one of which was also marked by difficult intubation and cardiac arrest. Another example of this situation led to subcutaneous em-

Table V. Maternal deaths from anesthetic misadventures

Type or mechanism (puerperal interval)	Anesthesia, medications	Delivery route	No. of cases

physema during salpingectomy for ectopic pregnancy. The final case was a cardiac arrest during intubation for puerperal tubal ligation.

6.3.1 Miniabstract 11

The patient was a 23-year-old primigravida at term. No evidence of gestosis was present. Onset of labor was spontaneous and no oxytocin was used. Transient fetal bradycardia was seen at 7 cm cervical dilation; artificial rupture of membranes revealed meconium staining of the amniotic fluid. Two distinct spinal anesthetics were administered 5 minutes apart; delivery occurred 15 minutes after the second spinal. The 3430 gm infant did well. The mother died 10 minutes after delivery. Autopsy uncovered neither congenital heart disease nor amniotic fluid embolization. The possibility of sickle cell crisis was not specifically addressed but seems unlikely from the available information. This appears, in retrospect, to be a clear example of medullopontine spinal anesthetic effects from a double dose of agent. The patient had not been intubated for ventilation.

6.3.2 Miniabstract 12

The patient was a 30-year-old primigravida at term. She was obese, weighing 122 kg (273 pounds), and was a pack-a-day

smoker. Borderline gestational diabetes mellitus was present. After 14 hours of oxytocin induction, the cervix was dilated 4 cm with a high presenting part. Two spinal anesthetics were attempted, but neither seemed to provide anesthesia for the contemplated abdominal delivery. Intubation for nitrous oxideether anesthesia was also unsuccessful, and the mother went into cardiorespiratory arrest. Resuscitation failed. Section delivery began a few minutes before the mother was declared dead, but she was in a late agonal state. The infant survived. Autopsy revealed hepatosplenomegaly of uncertain cause, nodular goiter, and acute renotubular necrosis. Some renal tubular regeneration was present, indicating an antepartum lesion or injury not otherwise identified. The possibility of environmental toxic exposure was not considered. The underlying metabolic problem and the renal lesions undoubtedly were burdensome, but the terminal events were set in motion by attempted anesthesia. The case has elements of a complex pathogenesis that will be discussed in Section 7.3 later.

6.4 Congenital cardiovascular disease (7 cases)

This group presents some of the most challenging prospects for future consideration. Six women died in

^{*}Combination of opioid fentanyl citrate and neuroleptic droperidol.

Table VI. Maternal deaths from pulmonary thromboembolism: special added factors

Embolism, not in labor			3

Otherwise unremarkable	. 5		

the final 7 years of the time-limited study. The sole exception occurred in 1968 with the principal lesion of ventricular septal defect. The patient was a 21-yearold, gravida 1, who was delivered by low forceps in the thirty-ninth week with the use of spinal anesthesia. No surgical repair of the heart had been done, she was known to have pulmonary hypertension, and the hemoglobin was often above 16 gm/dl. The early puerperium was apparently unremarkable when cardiac arrest occurred 85 hours postpartum; she died an hour later.

All but one of the remainder are similar. The unifying point is pulmonary hypertension, sometimes as part of Eisenmenger complex and sometimes with other cardiac anomalies. The women were of low gravidity, 1 or 2, and none of the secundigravidas had living children. They were at or near term and went through labor without difficulty. The postpartum cardiovascular adjustments appear to have imposed an irretrievable burden, and the other five women died at 48 hours and from 3 to 8 days after giving birth. An interesting finding, of possible relevance, is that several of these patients suffered both fever and chills after delivery. No specific localizations of infection were found in any of these cases. Their ages ranged from 20 to 24 years.

The seventh case was somewhat different. This was a 31-year-old woman, gravida 4, para 3, who died rather suddenly 10 weeks after giving birth. She was found to have Barlow's syndrome, mitral valve prolapse, along with patent foramen ovale. Although a population-at-risk statement is not possible from this experience, clearly established pulmonary hypertension will mean a difficult puerperal interval irrespective of its origin. This is significant for preconceptional counseling.

6.5 Pulmonary thromboembolism (16 cases) A time sequence of these cases is provided in Table VI. The three women not in labor all had additional predisposing conditions. Pelvic surgery is a known factor in the development of pulmonary thromboembolism for both men and women. The added changes in some clotting factors caused by pregnancy accentuate this risk. This accounts for two of these cases. One of them was barely into the second trimester at 17.5 weeks. Autopsy indicated preliminary episodes of multiple small pulmonary embolizations.

The third woman not in labor has a different sort of risk. She had severe bilateral saphenous and varicose femoral venous disease. The hematocrit was only 18%, the hemoglobin 5.7 gm/dl, and the blood urea nitrogen was 97 mg/dl. Massive pulmonary thromboembolism occurred in the twenty-seventh week of gestation. No prenatal care had been sought; she spoke no English. Her Iberian origins strongly suggested a concurrent Cooley's anemia in retrospect, but this was not considered during the brief medical contact before death. The elevated blood urea nitrogen was likely due to the occasional pyelonephritis accompanying thalassemic syndromes.

The time frame for puerperal pulmonary thromboembolism is of particular interest. For practical purposes the earlier group, 21/2 to 50 hours postpartum, does not overlap the period of amniotic fluid embolization, although in the latter syndrome women do not always die at the time of the event (Section 5.2). The late group includes some markedly delayed effects, 28 and 50 days were the two longest puerperal intervals. The patient who died 50 days after giving birth had an unusual location for thromboemboli, the left renal vein, with associated early infarction of the left kidney and left adrenal infarction.

These women tend to be in their middle thirties with appropriate high gravidity. Gravida 6, 7, 10, and 12 are represented, with reduced parity, 3, 4, 8, and 7, respectively. To some extent the younger mothers

showed a similar fall off of parity. For example, one woman was age 27 years, gravida 3, para 0; another was 20 years old, gravida 5, para 2.

6.5.1 Miniabstract 13

The patient was a 27-year-old woman, gravida 3, para 0, abortus 1, termination 1, at purported term. She weighed 123 kg (273 pounds) and was 155 cm (61 inches) tall. Her blood pressure ranged about 140 to 150/90 to 100; she had lost 9.8 kg (22 pounds) to this time and showed variable proteinuria. There was meconium stain at time of artificial rupture of the membranes and a section was done after onset of fetal bradycardia. For 5 days she had a low-grade fever without localization. On the sixth day the groin became red. On the eighth day superficial thrombophlebitis occurred, and on the eleventh day chest pain developed. Immediate embolectomy was performed, and a vena caval tent and aortic balloon were inserted without effect. She died shortly after surgery. The infant weighed only 1800 gm and was considered appropriately proportioned for size, suggesting that the pregnancy was short of term. The infant survived. There was a large saddle embolus in the main pulmonary arteries.

Comment: In many ways this case is in a poorly defined middle range sequence, a period after delivery in which no specific disease seems to arise, despite some unusual clinical features, for example, extreme obesity. The low-grade fever may have kept her in the hospital (many patients these days might be at home before the sixth day), but that did not avert a disastrous outcome.

6.5.2 Miniabstract 14

The patient, a 36-year-old, gravida 5, para 4, was a two to three pack-a-day smoker with chronic bronchitis. She weighed 105 kg (235 pounds). The first four pregnancies were uneventful. Vaginal bleeding occurred in the twenty-third week of pregnancy and then again in the twenty-sixth week. She was seen in silent labor and was found to be with twins. Twin A delivered spontaneously after which there was a brief delay; the head of twin B was in the vagina and the body was in the lower uterine segment at the time of massive fatal pulmonary thromboembolism. Twin A survived only 2 hours; the birth weight was 510 gm. Twin B died with the mother. It was not weighed but must have been smaller because it was only 18 cm long from crown to heel. Autopsy revealed lymphocytic thyroiditis in addition to the obesity and bilateral pulmonary thromboembolism.

Comment: One feature in common with the previous case abstract is whole-body obesity. This seems to be a risk factor for thromboembolic events. The volume capacity of the deep veins of the lower body and legs is enhanced by obesity; relative inactivity occasioned by body bulk may also be important here.

There was one patient who died of pulmonary thromboembolism in whom autopsy revealed a large renal hamartoma, or angiomylipoma. This was as large as a kidney itself. There was no evidence of thromboembolism arising from the tumor. The patient had had a splenectomy many years ago for congenital hemolytic anemia. This tumor has been implicated in maternal death through spontaneous rupture.¹⁷

6.6 Renal failure (2 cases)

Both patients had end-stage nephrosclerosis. One patient was a 39-year-old, gravida 8, para 4, abortus 2. She was admitted in the fortieth week with 50 mg/dl proteinuria. Progressive labor led to spontaneous delivery of a surviving infant using spinal anesthesia. A first-degree vaginal laceration was present. The past history suggested a diagnosis of "nephritis" 6 years earlier. Preterminal blood urea nitrogen was 140 mg/dl; creatinine was 7.5 mg/dl. Neither peritoneal lavage nor hemodialysis had any beneficial effect. Marked facial edema occurred agonally. She died on the twenty-seventh puerperal day. Autopsy revealed progressive nephrosclerosis, marked fibrinoid arteriosclerosis, and many cortical and medullary intrarenal casts. Both kidneys were small, weigning 145 gm together. The lungs were massively wet, weighing 1950 gm jointly. Microscopically a typical uremic pneumonia was present.

The other patient was a 28-year-old, gravida 7, para 6, also in the fortieth week of pregnancy. Urine albumin had been as high as 900 mg/24 hours. She was hypertensive. She had a previous term stillborn. Her weight went up an unknown amount to 85 kg (190 pounds). At full cervical dilation a spinal anesthetic using mixed pontocaine and xylocaine was instituted; the membranes were ruptured shortly thereafter revealing a large volume of green fluid. Ten to 20 seconds later she became apneic; cardiac arrest followed. The 3544 gm infant was immediately delivered by outlet forceps and did well, with an Apgar score of 6. The mother died 55 minutes after delivery. Autopsy showed latestage mixed renal disease with pyelonephritis, arteriolar nephrosclerosis, and large vessel arteriosclerosis. Careful search of the lungs failed to demonstrate any amniotic fluid embolism (AFE) or meconium deportation.

Despite matching the profile of AFE, this second patient seems to have had another pathophysiologic disturbance. In retrospect, the possibility of high spinal anesthesia seems a useful alternate mechanism, but no unusual sensorium was commented on in the medical record. This might have been obscured by onset of the agonal state. The renal lesions, on review, seem as severe as those in many patients dying of primary renal failure, albeit this death is not one readily so attributed except by absence of some other more compelling cause. With only two cases at hand, no profile of renal failure in late pregnancy is possible. The first case is one of obviously progressive renal failure; the second is perhaps best considered an example of combined abnormalities in which underlying renal disease added to the stresses and challenges of labor, anesthesia, and delivery.

6.7 Obstetric infection with sepsis (16 cases)
This particular category is related to the cases dis-

Table VII. Maternal deaths from infection/sepsis arising from pregnancy: Puerperal endometritis with extension and/or sepsis

Localization (puerperal interval)	Principal organism (s)	Delivery route	No. of cases
Placenta accreta (2.8 hrs)	Aerobacter	Vaginal	1 (1)
Postabortal		8	. ,
(9 hr)	Clostridium	Surgical (*)	1
(47 days)	Clostridium, Bacteroides	Surgical (*)	1
Postintrauterine contraceptive device		0 ()	(2)
Peritonitis and sepsis (50 hr)	Streptococcus	Hysterectomy at 13 wk	1
Septic myocardial infarction (16 days)	Escherichia coli	Vaginal at 23 wk	1
Puerperal sepsis (5 hr) Placenta caught in vagina, first admission 3 days earlier			(10)
Bacteroides, Staphylo	ococcus	Vaginal	1
(11 hr) Amniochorionitis	Streptococcus	Vaginal	1
(5 days) Peritonitis	E. coli	Section	1
(5 days) Febrile seizures	Streptococcus	Vaginal	1
(10 days) Peritonitis	Colonic flora	Section	1
(14 days) Persistent sepsis	Streptococcus, Staphylococcus	Vaginal	1
(14 days) Pulmonary hemorrhage	Streptococcus	Forceps	1
(14 days) Breast abscess	? Viral syndrome	Vaginal	1
(16 days) Subdiaphragmatic abscess	Bacteroides, Streptococcus	Forceps	I
(23 days) Persistent sepsis	Proteus	Vaginal	1
Rectovaginal septal hematoma	Colonic flora	Vaginal	I (1)

^{*}Dilation and curettage.

cussed later in Section 7.7 and represents 30.8% of all cases ascribed to infection or sepsis as the principal pathogenetic mechanism. Placement in this group is based on infections arising directly in the reproductive tissues affected by pregnancy. Table VII lists a number of attributes of the 16 cases: tissue localization, time intervals, principal organisms, and route of delivery. The table makes clear that even in this era of intense antimicrobial therapy puerperal sepsis of the classical type still occurs. The proportion between section and vaginal delivery cannot be further examined as to significance in the absence of definitive data on the frequency of section births for the period. The Commonwealth of Massachusetts did not begin to maintain birth statistics of sufficient detail for general research use until 1969.8 More importantly, data records respecting section deliveries began in 1982. In 1982 14,677 infants were delivered by section of a total 75,749 live births, or 19.38%, a value so close to the 2 of 10 as to be indistinguishable. The rate for 1983 was 20.05%; for 1984 it was 21.03%; for 1985 it was up to 22.01%. Because the time interval chosen for study by the working party for this report considerably antedates this time period, these rates may exaggerate the situation. A sharper rise in use of sections was noted in the late 1970s so that a linear model does not pertain. The maternal death factor suggests no special predilection for severe puerperal sepsis with the use of section delivery, even though the accumulative death rate is somewhat higher than the aliquot of deliveries by section over this 20-year period.

Other infectious cases include two of the earliest recorded maternal deaths from intrauterine contraceptive devices in place, which led to regulatory action eventually removing them from the market. Placenta accreta represents a special form of acute puerperal endometritis but has been separated in the table for emphasis. The lesions of puerperal sepsis at autopsy are fairly characteristic. These are principally infected thrombi in the parametrial veins. In some cases a continuous thrombotic cord is seen in the ovarian veins extending right into the inferior vena cava. The placental site will show abundant thrombosis, active and subacute inflammation, and very often overt bacterial colonies. These are on the uterine mucosal surface, which is an unhealed placental site often beyond the reach of active circulation and thereby unaffected by antibiotics.

6.7.1 Miniabstract 15

This patient was a 23-year-old woman, gravida 4, para 3, delivered in the thirty-sixth week by outlet forceps under spinal anesthesia. One of the three prior pregnancies went to 36 weeks; the others were term. The prenatal course was fully normal except for the onset of labor, which produced a living infant weighing 2722 gm. She was discharged routinely. All the older children had chickenpox at the time of discharge, but the mother's own history on this was uncertain. She was readmitted 14 days after delivery with pain in the right leg, which had lasted for 3 days. Two days before readmission she had complained of hemoptysis. Right leg thrombosis was diagnosed; she was recognized to be in a highly toxic and septic state, had disseminated intravascular coagulation, and died soon thereafter of massive pulmonary hemorrhage. Both uterine and blood cultures were strongly positive for β -hemolytic streptococci. No evidence for varicella pneumonia was adduced at autopsy.

Comment: Some evidence exists to suggest that β-hemolytic streptococcal sepsis is on the increase or has become more common puerperally, as reflected in a clear rise in neonatal streptococcal sepsis. ¹⁶ Injured capillary endothelium in sepsis caused by this organism makes hemorrhage an extension of the profile of septic lesions, and the lung is a prime target. Although no evidence was found to implicate varicella, mixed or synergistic viral-bacterial infections are also suspect and should be considered in such overwhelming cases.

6.7.2 Miniabstract 16

A 22-year-old primigravida delivered spontaneously in the forty-third week of pregnancy under light inhalant anesthesia. The infant weighed 3572 gm and did well. The prenatal course was marked by spontaneous pneumothorax of unknown cause in the first trimester. Vaginal bleeding 1 hour postpartum led to discovery of a lengthy vaginal laceration and a hematoma forming in the rectovaginal septum. This grew rather large and the patient went into shock. Hypogastric artery ligation was used followed by hysterectomy and bilateral adnexectomy. The postoperative course was stormy; the patient went into shock and sustained renal tubular necrosis, hemiplegia, and ureteric obstruction requiring renal exploration. She died 42 days postpartum after sepsis from mixed colonic flora. Autopsy revealed an exposed ligature in the rectal mucosa around a major rectal artery and demonstrated severe confluent bronchopneumonia with abscesses. There was marked hepatomegaly with zonal necrosis. The exposed rectal ligature is an obvious chronic portal of entry for the mixed flora.

Comment: If ever there was an argument for careful surgical technique including close postoperative surveillance, this case is surely support. It also denotes the risk of laceration of the vagina without obstetric instrumentation. It is a reminder that posterior vaginal injury is tantamount to anterior rectal injury. The case also illustrates the sequences of persistent sepsis with the hazard of pulmonary localization of suppurative organisms. The presence of much blood in the rectovaginal septum also compounded the clinical problem because the breakdown of retained blood aids both aerobic and anaerobic organisms to become established.

7.0 Intercurrent disease or pregnancy an uncertain or minor factor

7.1 General

Slightly more than half of all maternal deaths for the time period 1966 to 1985 fall into this group (144 cases of 51.2%). As the general listing in Section 4.4 makes clear, this is an extremely diverse set of medical, surgical, and obstetric factors. Because the listing in Sec-

tion 4.4 is complete with respect both to categories and principal individual factors, additional tabulation will not be undertaken. The working party divided this large number of cases into 12 subgroups, a few of which are limited in both size and scope. The dominant subgroups, with their section designators, are accidental deaths, acquired heart disease, complex pathogenesis, nongestotic intracranial vascular incident, non-obstetric neoplasm, and infection and sepsis. At least two cases from each of these six subgroups will be abstracted.

A more precise attribution may be possible in the future when more is known about the influence on various organs and tissues of the pregnant state when intercurrent disease manifests. Several specific examples of this potential will be developed in each section pertinent to that subject.

7.2 Accidental deaths (24 cases)

The clearest pregnancy-related accidental death occurred when a 25-year-old woman in labor fell down a stairwell in a hospital. She had been lightly sedated initially, and during an interval when labor lessened, she apparently wandered onto the landing. She had multiple lacerations of the head, contusions, and a presumed concussion. She went rapidly into a fatal coma and was delivered of a 39-week living infant by postmortem section. The infant died a day later. Toxicologic studies showed blood levels of meperidine and secobarbital well below the therapeutic ranges.

The other accidents bear variable time relationships to pregnancy. In general the committee did not go beyond the stated facts of each case as they became known at the time. The working party engaged in limited psychologic autopsy interpretations. The first miniabstract for this section embodies this aspect.

7.2.1 Miniabstract 17

The patient was a 22-year-old, gravida 3, para 2, woman who had an uneventful obstetric prenatal history, labor, and delivery that was spontaneous using cyclopropane anesthesia. She was separated from her husband, possibly since before this pregnancy. The child was healthy and survived the incident that follows. Forty-four days after giving birth she was visiting a neighbor's home. Present were the host and his wife, this woman, and two other adult guests. At approximately 9 PM the host apparently left the living room. When he returned, he shot her, his wife, and both other guests, and then shot himself. The psychodynamic implications of this disaster offer several possibilities for follow-up, which was not done because the obvious perpetrator was himself a victim. A blood group profile of at least the woman, the host, and the child might have shown what would likely be concluded to be a selfish or psychotic motive on his part.

Comment: Several other homicides offer similar possible understanding. For example, why would someone seek to commit murder by hire 9 weeks postpartum?

Even more tragic in a way, a mute woman with congenital deafness reported "spousal" abuse by her livein male friend. These reports were not given credence by the local authorities until after she was found murdered by multiple stab wounds to the chest at about 20 weeks' gestation during her second pregnancy. The male friend was charged.

7.2.2 Miniabstract 18

The patient was a 19-year-old primigravida in the thirty-seventh week of pregnancy. She was one of several persons injured in a collision between a bus and a car that she was driving at 2 AM. She was admitted to the hospital at 3:20 AM; immediate laparotomy revealed rupture of both spleen and uterus, a lacerated liver, and the fetus and placenta lying free in the abdomen. Supracervical hysterectomy was done in extremis. The mother died several hours later from the effects of massive intraperitoneal hemorrhage.

Comment: Impact trauma from vehicular collisions may differ in specific ways because of displacement of organs during pregnancy. This case involved a steering wheel injury across the upper abdominal rim. The diagnosis and treatment of mass internal injury in pregnancy must contend with both the organ displacement phenomenon and altered vascularity. Fetal salvage was precluded by uterine rupture and abruption.

7.3Acquired or nonanomalous heart disease (13 cases)

Arteriosclerotic heart disease has major implications in pregnancy. We have already mentioned one patient with gestosis also showing familial hypercholesterolemia, severe coronary artery disease, and myocardial infarction. This group contains five other cases without the background of gestosis. This makes arteriosclerotic cardiovascular disease more common as a cause of maternal death than so-called gestational myocardiopathy of which only two cases were found during this 20-year period. The generally decreasing significance of rheumatic heart disease is reflected in only two related cases despite the higher frequency of the condition in the northern climate of Massachusetts. Single examples each of unusual forms of cardiovascular disease were found. One had Marfan's syndrome and aortic dissection, and one had kyphoscoliotic heart disease. The latter woman died 4 days after attempted intrauterine fetal exchange transfusion and 59 hours after section delivery of a stillborn fetus. There was one example of coronary artery dissection. This woman was a 35-yearold primigravida with a history of migratory polyarthritis and a diagnosis of rheumatic fever at age 5 years. She was delivered by section and received no penicillin after surgery. She died suddenly 62 days after giving birth. Autopsy reveals massive left ventricular myocardial infarction and congestive failure caused by a dissecting aneurysm of the left coronary artery. The senior author has seen this lesion twice recently in women of very similar ages, one a 36-year-old multigravida 7 years past her most recent pregnancy20 and the other also a 36-year-old woman of uncertain parity 1 week postpartum.

7.3.1 Miniabstract 19

The patient was a 21-year-old primigravida who had premature labor in the thirty-fourth week of gestation. Delivery was by low forceps under spinal anesthesia. Urinary tract infection manifested postpartum. She signed herself out against medical advice. Twelve cays postpartum she was seen again and had an apical systolic murmur. Two days later she had cardiac arrest but was resuscitated. A retrospective history revealed migratory joint pains and pharyngitis suggestive of a rheumatic component. A working diagnosis of acute mitral insufficiency was made, and a Starr-Edwards mitral prosthesis was used to replace the mitral valve. At surgery septic rupture of a mitral papillary muscle was found. She died on the nineteenth puerperal day, 4 days after surgery.

Comment: Urinary tract infection is a somewhat unusual, but not an unlikely, complication. It is probable that premature labor was due to the same factor of urinary tract infection. The placenta was apparently not examined for acute inflammatory disease.

7.3.2Miniabstract 20

A 35-year-old primigravida has "known" rheumatic heart disease since 5 years of age. Major episodes of migratory polyarthritis occurred at ages 21 and 27. She weighed 65 kg (145 pounds) and was 157.5 cm (62 inches) tall. She was delivered in the forty-first week by section using spinal anesthesia. A 3250 gm infant survived. No penicillin was used in the puerperium. She was readmitted in extremis, placed in intensive care, and died on the sixty-second postpartum day. Autopsy showed a dissecting aneurysm of the left anterior descending coronary artery, massive global infarction of the left ventricle, profound congestive heart failure, and acute renotubular necrosis. No evidence of rheumatic disease was found at autopsy.

Comment: The childhood diagnosis of rheumatic disease often seems suspect to pathologists with experience at autopsies on early middle life adults. Rheumatic and rheumatoid disease can take unusual forms on occasion, and dissecting aneurysm or hematoma of the coronary artery could very well destroy the primary rheumatic focus. Generally, extensive myocardial infarction more than 4 days postictal would make identification of Aschoff bodies difficult. This possibility was not addressed in the autopsy study in this particular case.

7.4 Complex pathogenesis (17 cases)

When pathologists reconstruct the probable sequence of events leading to death, they often find difficulty in weighing the complex factors. If a time sequence is well documented clinically or by prior biopsy or laboratory information, the task is simplified. In the opinion of the working party, one is often limited because of a lack of published prior experience in some particular combination of disorders or events. This is why we have attempted to display a range of lesion potential when the data so permit. Mining this particular set of cases is obviously a prolonged process, and we have chosen several challenging abstracts to illustrate this point. In some instances the complex matrix contains factors discussed elsewhere in greater detail. Classification at this point reflects the belief of the working party that the combination is the key factor and not the individual elements. This group also contains those diseases for which cause and pathogenesis remain unclear

7.4.1 Miniabstract 21

A 26-year-old woman of uncertain gravidity was diagnosed as having lupoid hepatitis^{22, 39} when she was 17 years of age. She carried chronically elevated serum globulins. In the estimated twelfth week of pregnancy she was admitted in extremis with signs of intraabdominal disease, possibly a ruptured viscus or mass hemorrhage. Shock gave way to coma. Autopsy revealed a ruptured saccular aneurysm of the splenic artery, chronic active lupoid hepatitis and postnecrotic cirrhosis, and about 900 ml of intraperitoneal blood. The fetus measured 5.0 cm crown to rump, within the range expected for 11 to 12 weeks' menstrual age.

Comment: Lupus erythematosus remains an enigma with varied manifestations. Because arteritis is a major component of the systemic disorder, it is entirely possible that this particular ruptured aneurysm and hemorrhage arose within the immunologic matrix of lupus erythematosus. The volume, 900 ml, is not enough in its own right to cause hypovolemic anemia leading to shock and death. This outcome must have been the result in part of the effects on the liver of the hepatitis and the ability of the body to respond to and modulate stressor amines, marshal the stores of glycogen, and expand the blood volume. This case is mostly questions; classification under complex pathogenesis seems warranted.

7.4.2 Miniabstract 22

A 31-year-old woman, gravida 3, para 1, abortus 1, was bearing twins in the twenty-ninth week of gestation. She was dyspneic and had signs of right heart failure. A section delivery was performed using an unspecified general anesthetic, and both twins survived. The mother did poorly after delivery and died 25 days later. Autopsy showed puerperal myocardiopathy, scleroderma lung, and chronic visceral congestion.

Comment: Although the survival period postpartum is greater, this case resembles those in Section 6.4 in which pulmonary hypertension and congenital heart disease combined to yield a poor prognosis. This is likely a dual effect of scleroderma, with myocardial fibrosis and interstitial pulmonary sclerosis. In cases of congenital heart disease the long-standing left-to-right vascular shunting produces an arterial component perhaps more immediately productive of right heart failure in the postpartum period. Here the obstructive vascular element is more peripheral and more diffuse.

7.4.3 Miniabstract 23

The patient was a 29-year-old woman, gravida 4, para 3, whose first three pregnancies all went to term; with infants weighing 2835 to 2892 gm (a remarkably narrow range of birth weights). In this fourth pregnancy she developed varicosities, 3+ pitting edema of the legs, 4+ proteinuria, and in the twenty-fifth week she became dyspneic. Iron depletion was noted; marrow erythroid hyperplasia was noted, and the blood pressure rose to 220/130. The diagnosis of lupus nephritis was made and steroid therapy was begun. Three weeks later she was delivered of a 680 gm stillborn infant. She did poorly, with progression of renal failure. Death occurred 36 days postpartum. The autopsy confirmed the basic diagnosis of lupus nephritis. Marked adrenal atrophy as a result of steroid use was found.

Comment: This is a more typical expression of systemic lupus erythematosus, renal failure. Lupus affects the placenta, and a lupus factor may cross the placenta into the fetus.^{23, 35} These matters were not examined in this case.

7.4.4 Miniabstract 24

An 18-year-old primigravida had signs and symptoms of acute appendicitis; the preoperative white blood cell count rose to 15,900/mm3, and an appendectomy was performed in the thirtieth week of pregnancy using a modified abdominal approach and spinal anesthesia. No aspiration of vomitus occurred at or after surgery. Pulmonary edema developed after surgery, and uterine contractions were treated with ritodrine hydrochloride. A questionable pulmonary embolus with pleuritic pain was noted. Two days after surgery the patient died suddenly and undelivered. Autopsy examination indicated fetal death 4 to 5 hours earlier. The surgical specimen showed only focal appendicitis. At autopsy there was focal acute peritonitis surrounding the duodenum and pancreas and segmental adult respiratory distress syndrome in the lung. The possibility of viral pneumonia could not be fully excluded because the case occurred at the end of a major influenzal season.

Comment: In retrospect the ritodrine was probably unnecessary because only Braxton-Hicks contractions were present. Adult respiratory distress syndrome produces lung lesions very similar to influenzal pneumonia before bacteria are superimposed.

Such examples of complex pathogenesis could be extended. The pecularity of some cases is also illustrated by the observation that two cases of sarcoidosis involving the heart occurred, and both cases occurred in the same year out of 20 cases.

7.5 Nongestotic intracranial vascular incidence (26 cases)

Intracranial vascular lesions such as medial defect aneurysms are generally considered more common in women,^{24, 52} whereas arteriovenous malformations are slightly more common in men in general²⁴ while marginally more common in women in the third and fourth decades of life.²⁴ Despite the much lower frequency of clinical manifestations of medial defect aneurysms in women,^{24, 25} the working party, based on prior experi-

ence, came to consider that serious complications derived from these lesions were accentuated by pregnancy. This group is placed here rather than in our second main category (Section 6.0), because of the relative lack of basic tissue studies on the effects of pregnancy on the intracranial arterial system. However, 16 proven or very strongly indicated medial defect aneurysms (those indicated are by x-ray studies absent autopsy confirmation) and five arteriovenous malformations appear to us to be an astonishingly large number in 281 maternal deaths, given the age range and the expected natural history of these lesions.24, 25, 52 The combination is 7.5% of the whole. The known cardiovascular adaptations of pregnancy, in terms of volume and pressure,14 are deemed to augment changes in the vascular wall with net weakening, leaks, and rupture. Likewise, changes in coagulation factors²¹ combined with swings in blood volume or viscosity would predispose either to sinus or arterial thrombosis, accounting for four more patients in this subgroup.

7.5.1 Miniabstract 25

A 28-year-old primigravida with a known patent foramen ovale, who weighed 76.8 kg (172 pounds) and essentially had an unremarkable prenatal course until the thirty-seventh week of gestation, went into labor. Twins were delivered spontaneously with local anesthesia. Presumptive pulmonary thromboembolism occurred about 5 hours postpartum. Heparin therapy was instituted, but central nervous system signs developed, and the patient died on the thirteenth puerperal day. Autopsy revealed hemorrhage in the right cerebral hemisphere and thrombosis of the pelvic and ovarian veins. Widely patent foramen ovale was confirmed. The blood clot in the right hemisphere was a large, irregular $7 \times 7 \times 8$ cm mass. No evidence of arteriovenous malformation was found. An embolic occlusion of the right anterior cerebral artery was found. A diagnosis of paradoxic embolization was made.

Comment: Paradoxic embolization through a foramen ovale is rare. This case is considered to qualify in this section because primary thrombosis was limited to the pelvic region, and the blood clot in the right anterior cerebral artery was clearly an embolus. Interestingly, no embolization of the lung was found.

7.5.2 Miniabstract 26

The patient was a 48-year-old woman, gravida 8, para 4, abortus 3. The most recent delivery was at age 38 years and at 38 weeks' gestational age. The four infants weighed from 3175 to 3629 gm; the infant of the index pregnancy weighed 3884 gm. Birth control hormones were used for a 4-year period ending 3 years before this pregnancy (ages 41 to 45 years); during the interval she had no menses. Five years before confinement the diagnosis of essential hypertension, blood pressure surging to 220/110, was made with a treatment regimen including aldomet and thiazides. These were discontinued after pregnancy was diagnosed. During pregnancy, blood pressure was about 145/90. Labor was managed by amniotomy and oxytocin augmentation. The blood pressure went to 158/110 and later to 178/110. Delivery in the fortieth week was spontaneous using local anesthesia. She was discharged on the sixth puerperal day but collapsed shortly after arriving home. On readmission signs of intracranial bleeding were noted, with progressively increased intracranial pressure. Death occurred 12 hours after readmission. Autopsy showed massive subarachnoid hemorrhage arising from an aneurysm of one posterior cerebral artery, and a large cerebellar hemorrhage. The heart weighed an increased 410 gm and showed biventricular hypertrophy typical of chronic hypertensive disease.

Comment: The association between pregnancy and various intracranial vascular changes needs further exploration.

7.6 Nonobstetric neoplasms (16 cases)

The general subject of malignancy during pregnancy has been reviewed by McGowan²⁷ and others.^{35, 53} Of the list of tumors in this experience, two suggest some more particular relationship to pregnancy, pheochromocytoma and astrocytoma. The former would bear clinical recognition about a possible association because of the role of hypertensive disease in pregnancy.

7.6.1 Miniabstract 27

A 36-year-old woman, gravida 3, para 0, abortus 2, had an apparent diagnosis of gestosis, probably superimposed on borderline essential hypertension. There was trace proteinuria. The blood pressure in early pregnancy went up to 180/110. At 30 weeks' gestation the pressure reached 220/110. A significant psychologic overlay was present in the opinion of a consultant psychiatrist with special reference to blood pressure "cuff anxiety," which delayed hospitalization. Signs attributed to hypertensive encephalopathy developed. The blood level of epinephrine was measured at 51,000 pg/ml (normal, 20 to 97 pg/ml) and norepinephrine at >42,000 pg/ml (normal, 120 to 310 pg/ml) shortly before she died, undelivered, from cardiopulmonary arrest. Autopsy revealed a large left adrenal pheochromocytoma weighing 62 gm; a similar, but smaller, tumor on the right measured 1.2 cm in greatest diameter. The final admission lasted only 71/2 hours, with fetal death recorded 5 hours before the patient died.

Comment: The other example of pheochromocytoma had similar features of clinical course, including an apparent lack of appropriate credence by some health care professionals about the seriousness of the problem.

7.6.2 Miniabstract 28

A 30-year-old woman, gravida 2, para 1, with an uneventful first pregnancy, had weakness of the left side of the mouth, dizziness, and headache. The early signs were present at 24 weeks' gestation and progressed to headache by 34 weeks' gestation. Three days before delivery in the thirty-fifth week of gestation, Bell's palsy developed and the patient became restless. Hemiparesis then occurred. Section delivery was done essentially at the same time as craniotomy. This revealed a large right temporal lobe mass histologically astrocytoma, grade 3. Death occurred 48 hours postpartum. The 2722 gm infant survived.

Comment: The other three cases of astrocytoma had

a number of features in common with this one. One patient was known to have temporal lobe epilepsy and was admitted with "personality changes." She was a 31-year-old woman, gravida 1, in the thirty-second week of pregnancy. She was obtunded on admission and craniotomy and delivery occurred while she remained comatose. The fetus was stillborn, weighing 2155 gm. There was a large right temporal lobe astrocytoma, grade 4, with extensions into both the right and left lateral ventricles. The other two cases were at comparable stages of pregnancy, decompensated in similar ways, and had similar, almost immediate, outcomes. Indeed, the profile of this process is almost so narrow as to serve as a diagnostic matrix if one did not have much in the way of confirmatory tissue evidence.

Of the remaining malignant processes observed in this series, the two patients with mammary carcinoma deserve brief mention. One patient was 44 years old, and the other was 30 years old. Both pregnancies concluded prematurely, one by section and the other spontaneously after an intense course of radiation. Interestingly, the fetus delivered by section died neonatally, and the other survived.

7.7 Infection or sepsis (36 cases)

The patients discussed here relate to those described in Section 6.7 and represent the larger share (69.2%) of all infectious or septic processes in the overall study. Within this group, the largest subgroup is pneumonia, with and without other localizations of the infectious process. This accounted for 10 of the 36 patients. Six specified forms of viral disease were found: hepatitis (four), varicella myocarditis (one), and herpes encephalitis (one). The other major subgroup was endotoxemia from coliform organisms, with related attributes such as intestinal obstruction and peritonitis.

7.7.1 Miniabstract 29

The patient was a 28-year-old woman, gravida 2, para 1. The first pregnancy was uneventful as was the prenatal course in the second until approximately 25 weeks' gestation. At that time the patient noted multiple red skin spots similar to flea bites. Four days later she fell without apparent reason; 3 days later she complained of headache and weakness. She was hospitalized 2 days before delivery after a seizure. Labor began; a 1000 gm infant was delivered spontaneously but lived only 3 hours. The mother died 9 days after delivery. Autopsy showed herpes simplex encephalitis, proved by viral culture, and necrosis of both temporal lobes.

Comment: Herpes simplex infection is an intercurrent infection for pregnancy not often manifested in this fashion, raising the unanswered question about this patient's individual immune competence. The mechanism of onset of labor in the face of evolving encephalitis and other infectious processes remains obscure. Fetal or neonatal outcome will be based on the mixture of gestational immaturity and the depth of maternal sepsis, shock, or nutritional stress.

7.7.6 Miniabstract 30

The patient was a 23-year-old primigravida who had an uneventful prenatal course except for cystitis with positive urine culture (Escherichia coli) at colony count >100,000. She went into labor in the forty-third week of gestation and sustained a deep third-degree laceration with complete tear of the anal sphincter. This was repaired, but perineal sepsis developed. After a stormy course, she was discharged home but came back the next day with signs of pulmonary thromboembolism; some emboli might have been septic. The inferior vena cava and ovarian veins were ligated 16 days postpartum. Pericardial effusion and adhesions then developed. During attempted pericardiolysis the intrapericardial segment of the inferior vena cava ruptured, and the patient died 24 days postpartum. Autopsy revealed septic phlebitis at the site of vena caval tear and organizing serosanguineous pericarditis. The 2948 gm infant survived.

Comment: This case is included to show the range of possibilities in bacterial sepsis in the parturient woman. The infant was not large, and most third-degree lacerations will heal, albeit sometimes slowly. It is evident that a pathogenetic mechanism akin to ordinary puerperal sepsis was at work here in the pelvic veins, but seemingly from a different portal of entry unlike the usual endometrial implantation site. Nevertheless, this case could well be classified in group 2 rather than here, were it not for the highly unusual terminal events and the longer postpartum interval without obvious endometrial signs.

7.7.3 Miniabstract 31

A 30-year-old woman, gravida 5, para 4, had three successive births at 37 weeks' gestation with birth weights of 2722 to 2948 gm; the fourth was at 40 weeks' gestation, also at 2948 gm, but this last child died of neonatal respiratory distress. The mother was diagnosed as having chronic ulcerative colitis, which worsened greatly in her fifth pregnancy, especially beginning in the twenty-seventh week with evidence of multiple colonic perforations and peritonitis. She continued to be febrile and went into labor in the twenty-eighth week; total colectomy was performed 2 days after delivery. Nine centimeters of terminal ileum were removed along with the whole colon. A stormy course led to death 9 days postpartum and 7 days after surgery. Autopsy revealed gastric stress ulcers, residual peritonitis, and bilateral acute bronchopneumonia. The 971 gm infant died after several hours of evident respiratory distress.

Comment: The relatively large inoculum into the peritoneal cavity from multiple colonic perforations poses a special dilemma in pregnancy because of the usual mild suppression of immune mechanisms. Total colectomy is a formidable undertaking as well but has less intrinsic negative nutritional potential for a continuing pregnancy than does extensive surgical bypass of the small intestine.⁵¹ Pregnancy is a complicating factor in this case. The working party accorded it a lesser role, one of aggravation rather than causation, because the disorder appeared during an interpregnancy interval.

7.7.4 Miniabstract 32

The patient was a 38-year-old woman, gravida 7, para 6. Little was known about her previous pregnancies, and she received no prenatal care for the seventh pregnancy. She weighed 111.6 kg (250 pounds) and was 162.6 cm (64 inches) tall. On admission she was noted to be anemic (hemoglobin, 8.9 gm/dl) and hypertensive (150/90). Delivery was spontaneous without anesthesia, and the 3714 gm infant survived. She was discharged home in apparent good condition, but on the sixteenth puerperal day, a cough and fever developed and were treated with antibiotics. Three days later she collapsed, was readmitted to the hospital, and died 5 hours later. Autopsy revealed advanced bilateral influenzal pneumonia (right lung weight, 1050 gm; left lung, 975 gm) and hypertensive cardiovascular disease (heart weight, 550 gm, with left ventricular hypertrophy).

Comment: This death occurred during the usual late winter epidemic season in an especially severe year for influenza.

7.8 Sicklemic-thalassemic manifestations (3 cases) These are uncommon causes of maternal death. Two of the three cases were conjoint sickle cell-beta-thalassemia, but which type beta-thalassemic hemoglobin is unknown. One was a 25-year-old secundigravida who took an overdose of propoxyphene for pain. She had chronic symmetric arthritis at age 5 years and back and retrosternal pain. Chronic anemia was present. Delivery was by section in the thirty-third week; the 2270 gm infant lived only 36 hours. The mother died 30 days postpartum in medullary bone sickle cell crisis. Small marrow emboli were found in the lung and postmortem x-ray films revealed aseptic hip necroses.

The other sicklemic-β-thalassemic case was further complicated by deficiency of glucose-6-phosphate dehydrogenase, thromboses, infection, femoral head necroses; the patient lived 27 days postpartum after delivering a surviving infant at 40½ weeks' gestation.

The third example with sicklemia was also complex. The patient had a history of rheumatic disease and multiple manifestations of the underlying hemoglobinopathy. Seizures denoted the cerebral thrombosis, which was found at autopsy. Death occurred late in the second trimester, with the patient undelivered.

7.9 Status asthmaticus (2 cases)

Status asthmaticus is an uncommon cause of death generally and unusual in this series of maternal deaths. One fatality occurred 77 days after the patient gave birth. The patient was 35 years old and had six essentially normal earlier pregnancies. During the final pregnancy, her asthma was relived. Death occurred in mid-November. The other patient was a 25-year-old woman, gravida 8, para 4, termination 3, with known heroin and alcohol abuse, past asthma, and pelvic inflammatory disease. She was admitted at 311/2 weeks' gestation with a severe asthmatic attack, was treated, and was released. She was rushed to the hospital a week later with another severe attack but was dead on arrival. Postmortem section was done immediately but produced a stillborn fetus. Blood toxicologic studies revealed only a therapeutic level of quinine. Because no quinine had been prescribed, it is likely the patient obtained it as part of a substitute street drug.

7.10 Thrombotic thrombocytopenic purpura (4 cases)

These cases share various aspects of a clinical profile, but not all features were found in all cases. Three of four patients were primigravida; three of four patients were late in the second trimester and did not die in labor; and three of four died with specific hemorrhagic complications. The fourth patient was more complex in each aspect. One patient gave birth in the thirtysecond week of gestation and died on the twelfth puerperal day. One patient was gravida 7, para 6, and carried twins; death was due to ruptured subcapsular hematoma of the liver. One patient had severe chronic renal disease with strong features of lupus nephritis.

7.11 Thyrotoxicosis (1 case)

This 19-year-old woman was probably a primigravida with a known past history of thyrotoxic attacks. She was taking propylthiouracil. Jaundice was present for 10 to 14 days. She was admitted in the twelfth week of pregnancy with fulminant hepatic failure. Autopsy revealed a 100 gm thyroid with diffuse hyperplasia. There was hepatocellular necrosis and regeneration, bile duct proliferation, and no central veins in the areas of nodular regeneration. It is uncertain whether this was ordinary infectious hepatitis or the early phase of acute yellow atrophy of the liver seen infrequently in thyrotoxicosis.9, 12, 31, 43

7.12 Toxic pancytopenia (1 case)

The patient, a 16-year-old primigravida with folic acid anemia, had multiple trace urine albumin tests and acknowledged her poor compliance with her folate prescription. She delivered spontaneously in the forty-second week of pregnancy under general anesthesia involving nitrous oxide and thiamylal. The hematocrit level fell from 25% to 18%, and hemoglobin decreased from 13.2 to 6.7 gm/dl. A bleeding diathesis developed, and 5 U of platelets were given during labor. Hypersegmentation of polymorphonuclear leukocytes was prominent. Postpartum the course was marked by gross hematuria, sepsis, and pancytopenia (2000 white blood cells/mm3). The terminal event was occasioned by adult respiratory distress syndrome and brain death for 4 days before somatic death 12 days postpartum. The unifying component of this case is the further suppression of vitamin B₁₂ and folate metabolism by nitrous oxide anesthesia.8.41

7.13 Unclassified (I case)

The patient was a 29-year-old gravida 8, para 6, abortus 1, carrying triplets, which all delivered spontaneously at 371/2 weeks under light inhalant anesthesia. The triplets weighed 2268, 1814, and 2041 gm in birth order. All three survived. The mother died 48 days postpartum after an uncertain period of an illness characterized by constant vomiting. There was a possible episode of vomitus aspiration. A local medical examiner viewed the body but did not perform an autopsy, leaving unknown the nature of this unobserved puerperal death.

8. Pathologic investigation of maternal deaths

It is ironic, but not unexpected, that the one case unclassified out of a series of 281 maternal deaths (Section 7.13) was one in which an autopsy would have been of great material assistance in finding an explanation for the outcome. Several possibilities come to mind, especially to the minds of the working party after their extensive review of this experience. One would be puerperal myocarditis or myocardiopathy. Another, given the season of death, would be influenzal pneumonia. However, the more important point to be made here is that the more information available in every and any case the more likely (1) the death will have a cogent explanation, and (2) the greater will be the contribution of the insights of that case to our understanding of the morbid pathophysiology of pregnancy generally. The notes of the working party reflect from time to time the statement "... really needed an autopsy on this case . . ."

We return to our initial treatment of the definition of maternal mortality, in which we differ from the proposed consensus statement. The actual number of maternal deaths has fallen, not necessarily to an irreducible minimum, but certainly to a gratifyingly lower rate than when Dr. Jewett began his work. With the current societal restraints on costs of medical care and the improvements in obstetric care in particular, more and more parturient women are sent home earlier. In accordance with the obvious, a higher proportion of maternal deaths will occur out of hospital and might possibly seem to fall into the jurisdiction of medical examiners or coroners. It is one purpose of our study and this review to provide such physicians and pathologists with the broadest understanding of the possibilities inherent in a maternal death. With respect to the forensic needs of such cases, few are obviously accidental or criminal. We found eight deaths from vehicular collision and five deaths from homicide. There was only one death in which possible negligence of health care personnel was a factor, and only one other attributed to"probable suicide." Finally, one death occurred after a fall during a serious house fire. Many of these cases are medically and obstetrically complex and "viewing the body" is an insufficiently scientific approach to the needs of the matter. Most cases are medical problems, ones in which the medical profession, in general, and medical examiners, in particular, share a common need to know, which suggests the basis for cooperative enterprise.

October 1991

In one sense our society will be judged by the style, character, and direction of the care provided pregnant women, who represent our species at one of the most vulnerable periods of its life span.

Inherent in this point of view is the concomitant need to study each failure, each maternal death, with the fullest measure of present scientific and technical knowledge while expanding our avenues of interest and concern. The ultimate test of professionalism is the practice of dispassionate, comprehensive investigation to which the attending physicians must give as much allegiance as the consulting pathologist and the reviewing committees. To that end, one by which no case is diminished by being ignored, progress to 100% modern autopsy examination is just the first step. The second step is for all physicians and pathologists who might have or gain responsibility for performing and reporting these autopsies to make themselves better informed on the scope and essence of maternal mortality. We hope this report will be viewed as helpful to that

LETTERS TO THE EDITORS

Gonadotropin-releasing hormone agonist and estrogen-progestogen replacement therapy

To the Editors: We read Barbieri's article (Barbieri RL. Gonadotropin-releasing hormone agonists and estrogen-progestogen replacement therapy. Am J OBSTET GYNECOL 1990;162:593-5) with interest. There are a few points on which we wish to comment.

A number of articles on gonadotropin-releasing hormone (GnRH) agonist treatment and bone metabolism report divergent results influenced by small patient numbers, different doses and routes of administration, and methods and sites of bone loss estimation. Studies^{1, 2} in which the usual 6-month treatment was extended showed further bone mineral density reduction in the spine. That bone mineral density remained significantly below baseline level 6 months after treatment is not surprising because a substantial reduction in bone mineral density has been demonstrated in untreated women before menopause.³

There is no evidence that estrogen replaces lost bone, only that it prevents further loss. There being no long-term follow-up of the effects of GnRH agonist-induced bone mineral density reduction, the safety of protracted treatment must be questioned. In our opinion, treatment should be limited to periods shorter than the 2 years recommended by Barbieri. In the study justifying this proposal, half the patients were treated with estrogen; any patients who lost substantial bone mineral density were removed from the study and treated with estrogen.

Bone-protective roles for progestogen during GnRH agonist—induced hypoestrogenemia were examined in a study⁵ in which GnRH agonist was combined with norethindrone. Vasomotor symptoms were reduced, but bone mineral density of the lumbar spine was significantly reduced; similar results were seen with combined GnRH agonist and medroxyprogesterone acetate.⁶ Patients treated with combined GnRH agonist and medroxyprogesterone acetate with or without conjugated estrogen showed no difference in bone mineral density, but neither did the control groups treated with GnRH agonist alone (Barbieri). In these studies bone mineral density was measured on the appendicular skeleton, which is less sensitive to hypoestrogenemia that the spine.⁴

We agree that a regimen for combined GnRH agonist and steroid hormones is a major goal because many patients have problems associated with cyclic steroid changes. Such a regimen should be simple to administer and should produce a stable and physiologic concentration of steroids without metabolic side effects.

We have used a combination of a depot GnRH agonist (Goserelin: ICI Pharma; 3.6 mg/mo) and a low-dose subcutaneous implant of estradiol (Organon Inc., 25 mg/6 mo), which has been shown to have bone-conserving effects and minimal metabolic disturbance. Fifteen women were treated; the plasma estradiol concentration was stable and within normal midfollicular

phase range. The profiles indicate that this regimen could form the basis of long-term therapy for problems such as premenstrual syndrome, irregular menstrual bleeding, and endometriosis and could also be used as an alternative contraceptive.

Reply

To the Editors: I am thrilled that my article stimulated Gudmundsson et al. to share their scientific ideas and clinical observations. We completely agree that a major goal of gynecologic endocrinology is to develop combined drug regimens of GnRH analogs plus steroid add-back therapy that would be effective in the treatment of endometriosis and myomas and that would minimize the loss of bone mineral density observed when GnRH analogs are used as a single agent.

Our research group was the first to report the results of a 6-month randomized, placebo-controlled trial of combined GnRH analog plus progestin therapy in the treatment of myomas. A member of our group, Dr. Friedman, was also the first to report the results of a small open clinical trial of long-term (27 months) combined GnRH analog plus estrogen-progestin therapy in the treatment of myomas. The experience gained in these clinical trials prompted us to propose the "estrogen threshold hypothesis." We believe that different organs (endometrium, myometrium, bone) have varying sensitivity to the stimulatory effects of estradiol and progesterone. For example, an estradiol concentration of at least 40 pg/ml may be required to stimulate the

Letters 1157

Volume 165 Number 4, Part 1

growth of endometriosis implants. In contrast, an estradiol concentration of approximately 30 pg/ml may be sufficient to prevent partially the bone loss often associated with a severely hypoestrogenic state (estradiol concentration of 10 pg/ml). If the estrogen threshold hypothesis is valid, there may be a "therapeutic window" for estradiol in the range of 25 pg/ml to 35 pg/ml in which estrogen-dependent diseases such as endometriosis are suppressed, but in which cumulative bone loss is minimal.

A critical observation made by Dr. Friedman² is that it may be wise to treat with a GnRH analog alone for approximately 3 months before adding estrogen and progestin to the regimen. With this sequential regimen, the estrogen-dependent disease may be forced into hibernation by the GnRH analog treatment and consequently be less responsive to the estrogen-progestin add-back.

An important observation is that treatment of premenopausal women with GnRH analogs for 6 months produces a 6% loss in lumbar vertebral body trabecular bone density and that most or all of this loss is regained within 6 months after GnRH analog therapy is discontinued.⁴ I believe that these findings support the hypothesis that estradiol and progesterone secreted by the ovary can produce an increase in bone-mineral density after premenopausal women are exposed to a short period of hypoestrogenemia.

Neurologic versus behavioral neonatal assessment after birth asphyxia

To the Editors: We read with interest the report of a study designed to define the threshold of asphyxia beyond which central nervous system damage becomes manifest (Low JA, Muir DW, Pater EA, Karchmar EJ. The association of intrapartum asphyxia in the mature fetus with newborn behavior. AM J OBSTET GYNECOL 1990;163:1131-5).

While we agree with the authors when they state that a proper examination of the relationship between thresholds of asphyxia and outcome requires an accurate diagnosis of fetal asphyxia and a reliable measure of central nervous system injury, we are concerned by their choice of the Neonatal Behavioral Assessment Scale (NBAS) as the outcome measure for this study. In support of this choice, they quote Tronick and Brazelton, who proposed that behavioral assessment in the newborn period may identify mild dysfunctions that are not apparent from standard neurologic examination. They appear to dismiss standard neurologic examination and state that objective measures of central nervous system injury in the newborn period are not available, in spite of published reports to the contrary.¹⁻⁴

In any event the results of this study completely contradict the proposal of Tronick and Brazelton. There were no significant differences between the results of the NBAS of the asphyxia and control groups. Furthermore, even the NBAS results of the four cases identified as encephalopathy by "clinical record of nurses and physicians" did not significantly differ from those of the controls. Should we infer that behavioral testing with the NBAS is insufficiently sensitive to detect neurologically abnormal infants or that it could not be applied to the sickest infants? Whatever the explanation, conclusions cannot be drawn about the very serious problem of thresholds in birth asphyxia from this study.

Reply

To the Editors: We welcome the opportunity to respond to the correspondence from Amiel-Tison and Stewart. We are in agreement with them regarding the importance of newborn encephalopathy as an indication of central nervous system insult. Standard neurologic examination is a normal function of our neonatal intensive care unit; this care includes continuous observation of newborn behaviour and tone with documentation of any subtle tonic or clonic seizures.

The incidence of metabolic acidosis at delivery (umbilical artery buffer base < 34 mmol/L) in our center is approximately 2%. There are a number of newborns with biochemical evidence of intrapartum fetal as-

1158 Letters October 1991
Am J Obstet Gynecol

phyxia who do not have evidence of newborn encephalopathy. In our follow-up studies these children, in relation to a control group, have shown an increased incidence of developmental, particularly motor, delay, as measured by the Bayley Scales of Infant Development at 1 year of age.² This suggests that a fetus may experience an acute intrapartum central nervous system insult caused by asphyxia without manifesting newborn encephalopathy.

Studies in the fetal lamb have demonstrated that the fetus that is subjected to sustained partial hypoxemia has important cardiovascular compensatory mechanisms that will maintain normal cerebral oxygen consumption for some time, although decompensation ultimately will occur with a progressive metabolic acidosis.³ We support the notion that corresponding compensatory mechanisms provide a period of protection for the human fetus. However, there is a threshold of asphyxia beyond which central nervous system injury, namely, motor dysfunction, will occur in the surviving child, and it may be accompanied by mental retardation. This threshold remains to be determined.

In this study the newborns of the asphyxia group, with the exception of one with severe newborn encephalopathy, represent the less severe part of the spectrum of intrapartum fetal asphyxia. Experience with the Brazelton NBAS administered by trained examiners suggested that this test might provide an objective measure of minimal central nervous system injury during the neonatal period. Thus the premise in this study was that the NBAS could be a means of identifying central nervous system injury after intrapartum fetal asphyxia was determined biochemically in these newborns without evidence of newborn encephalopathy.

Amiel-Tison and Stewart are correct in stating that this study does not define the threshold of birth asphyxia that is responsible for the neurologic deficits in children. However, this study suggests but does not prove that biochemically determined fetal asphyxia without associated newborn encephalopathy has not been sufficient to cause central nervous system injury. Future developments of more sensitive objective measures of newborn neuropathologic conditions may determine that the NBAS has been insufficiently sensitive to detect minimal central nervous system injury caused by asphyxia.

CA 125 in breast milk

To the Editors: With great interest I read the article by Hardardottir et al. (Hardardottir H, Parmley, TH II, Quirk JG Jr, Sanders MM, Miller FC, O'Brien TJ. Distribution of CA 125 in embryonic tissues and adult derivatives of the fetal periderm. Am J Obstet Gynecol 1990;163:1925-31) describing the expression of CA 125 with immunohistochemical techniques in embryonic tissues and mammary glands. Furthermore, large amounts of CA 125 in colostrum and milk probes were reported.

To my knowledge the data on CA 125 levels in the colostrum and breast milk need to be analyzed further: Declining concentrations of CA 125 in human milk and serum post partum were published earlier. In this study, on the day of parturition we demonstrated elevations of CA 125 in the maternal sera of all patients. Thus an antigen transfer from the maternal bloodstream into the breast milk must be considered.

Hardardottir et al. failed to describe concomitantly measured maternal CA 125 serum concentrations; therefore a contribution of these values to the colostrum and milk levels must be emphasized.

Lothar C. Fuith, MD

Department of Obstetrics and Gynecology, General Hospital, Esterhazystrasse 26, 7000 Eisenstadt, Austria

REFERENCE

Reply

To the Editors: Recently we described the distribution of CA 125 in embryonic tissues and adult derivatives of the fetal periderm. Using immunohistochemical techniques we observed neticeable staining in the adult apocrine sweat glands and mammary glands. Antigen in frozen sections of lactating breast tissue was detected by the antibodies OC 125 and M11, which recognize different epitopes on the CA 125–carrying glycoprotein. The antigen was found to be localized intraductally in the breast, as opposed to intracellularly. Because of the intraductal localization of the antigen, it was anticipated that breast milk might contain significant concentrations of antigen.

Previously Fuith et al.¹ reported ranges of CA 125 antigen levels in breast milk from 82 to 357 U/ml at 1 week after delivery and 25 to 308 U/ml at 6 weeks after delivery. We observed very high levels of antigen (15,000 to 60,000 U/ml in colostrum; 130 to 1788 U/ml in breast milk from 3 to 7 days post partum and 28 to 203 U/ml 5 to 25 weeks post partum). It also has been reported that relatively moderate increases in serum CA 125 occur after delivery (48 to 500 U/ml). Fuith et al.¹ and Itahashi et al.² attributed these transient elevations of serum CA 125 levels to infusion of antigen into the maternal circulation as a result of placental separation. We believe this is a plausible explanation. The data we present regarding very high levels of CA 125 in colostrum and the fact that antigen is

localized in the intraductal space of the mammary gland would support the notion that the milk antigen may be synthesized and secreted by the breast, just as antigen appears to be synthesized and secreted by both the apocrine sweat glands and the endometrial glands. Leakage of this antigen into the maternal circulation, thereby contributing to the postpartum serum levels, is possible but unlikely unless access of the CA 125 antigen through the endothelium to the circulation can be accounted for. The likelihood that serum antigen is the source of the CA 125 in colostrum also is unlikely because of the great disparity in concentrations between serum CA 125 and colostrum CA 125. Nonetheless, we believe that paired concurrent assays of CA 125 in colostrum and serum in the postpartum period would be useful in the support or denial of these conclusions.

Risk of open spina bifida

To the Editors: Genetic counselors try to provide couples with the best estimate of their risk of birth defects. With the implementation of maternal serum α -fetoprotein (AFP) screening programs, patients with elevated maternal serum AFP levels are referred to ultrasonography specialists to look for fetal open spina bifida and other lesions. Ultrasonographic examinations will show most of these patients to have normal fetuses. The revised numerical risk of a fetus having open spina bifida calculated on the basis of its mother's maternal serum AFP level plus normal results on ultrasonographic examination is important information that patients may want to use in deciding whether to accept the risk of amniocentesis. The figures presented by Thornton et al. (Thornton JG, Lilford RJ, Newcombe RG. Tables for estimation of individual risks of fetal neural tube and ventral wall defects, incorporating prior probability, maternal serum α -fetoprotein levels, and ultrasonographic examination results. Am J OB-STET GYNECOL 1991;164:154-60) are therefore potentially very useful.

My initial inspection of Tables II through IV focused on the upper of the three lines for each particular maternal serum AFP level. Each figure in this line "assumes that ultrasonography provides no information beyond maternal serum AFP" level. In other words, I presume the risk would be calculated solely on the basis of the maternal serum AFP level.

If the population incidence of open spina bifida is 1 in 1000, my reading of the tables indicates that a patient with a maternal serum AFP level of 2.0 multiples of

the median would have a risk of fetal open spina bifida of 1 in 1800. If the ultrasonographic information is excluded, how can a patient with an *elevated* maternal serum AFP level end up with a *lower* risk than the risk that existed before the screening test was performed?

Douglas W. Hershey, MD

Prenatal Genetic Services, Sutter Center for Women's Health, 5275 F St., Sacramento, CA 95819

Reply

To the Editors: I thank Dr. Hershey for his interest in our paper. At first sight it is indeed surprising that a woman with a maternal serum AFP level of 2.0 multiples of the median should have a lower risk of open spina bifida than if she had had no test at all. It is nevertheless correct. The posterior odds of open spina bifida are increased only when the maternal serum AFP likelihood ratio rises above unity. This happens when the curves of the maternal serum AFP probability distributions for affected and unaffected pregnancies cross. Fig. 1 in our article, a hand-drawn plot of the probability distributions, was only intended to illustrate the derivation of the likelihood ratio; the curves were drawn (inaccurately) to cross at 2.0 multiples of the median. The curves should cross at a maternal serum AFP level between 2.0 and 2.5 multiples of the median. Nevertheless it is easy to see from Fig. 1 that a maternal serum AFP level of 1.5 multiples of the median gives a likelihood ratio of <1.0; if the curves were drawn correctly, it would be clear that the likelihood ratio for a maternal serum AFP level of 2.0 multiples of the median is also <1.0.

The assumption that the risk of open spina bifida automatically increases if the maternal serum AFP is >1.0 multiples of the median is an error resulting from intuitionist thought. Dr. Hershey used the "representativeness" heuristic to calculate risk¹; because raised levels of maternal serum AFP are "representative" of open spina bifida, he assumed that the risk was raised. The truth is sometimes counterintuitive, but our tables should prevent this mistake in future.

Postnatal outcome depends on prenatal history

To the Editors: We read attentively the article by Lipper et al. (Lipper EG, Ross GS, Auld PAM, Glassman MB. Survival and outcome of infants weighing <800 grams at birth. Am J OBSTET GYNECOL 1990;163:146-50), and we wish to express the opinion that this study has no scientific meaning.

In particular, the weight of the fetus at birth is for obstetricians a topic of great importance and interest, and we should not forget to differentiate the weight of an appropriate-for-gestational-age newborn from the

weight of a growth-retarded fetus. All of the modern literature differentiates the postnatal outcome according to the prenatal history of the fetus.

The study of Lipper et al. brings confusion at a time when pediatrics and obstetrics are beginning to agree on the definitions of the terms.

A knowledge of the outcome of a fetus <800 gm is of no utility if we are not acquainted with the gestational period in which the infant was born.

Your JOURNAL usually is rightly critical in selecting studies coming from non-English-speaking authors, and we are astonished that it publishes with such simplicity data so barely scientific.

Claudio Giorlandino, MD

49 Viale Liegi, 00198 Rome, Italy

Reply

To the Editors: Although it is an important practice in neonatology to differentiate appropriate-for-gestational-age from small-for-gestational-age infants, our study only reported on survival and outcome of infants weighing between 500 and 799 gm at birth whose mean gestational age was 25.5 ± 1.8 weeks (see Table I of our article). Within this narrow range of birth weight and gestational age intrauterine growth retardation could not be a factor relating to outcome, as suggested by Dr. Giorlandino.

Anticomplementary activity in serum and abortion

To the Editors: We read with interest the article by Quinn and Petric (Quinn PA, Petric M. Anticomplementary activity in serum of women with a history of recurrent pregnancy loss. Am J Obstet Gynecol 1988;158:368-72). We would like to present our similar study of habitual abortions, preeclampsia, spontaneous abortions, endometriosis, and normal pregnancies. We performed complement fixation tests with cardiolipin antigen and tested the anticomplementary activity of the sera of these patients. Cardiolipin is a negatively charged phos-

pholipid abundant in mitochondrial membranes. The mitochondria are one type of activator of the complement cascade through the classic pathway.¹

Autoantibodies against cardiolipin cause extensive placental thrombosis and subsequent fetal losses. 2.3 Anticardiolipin antibodies have been detected in recurrent fetal losses, preeclampsia, and endometriosis. Thus it is possible for antibodies that form immune complexes with cardiolipin to activate the complement system and have an anticomplementary effect, as was shown by Quinn and Petric.

We had 50 patients with histories of habitual abortion (three or more abortions), 22 patients with histories of spontaneous abortion (fewer than three abortions), 6 patients with histories of late intrauterine fetal death, 26 patients with histories of severe preeclampsia, and 58 patients with histories of endometriosis. As control groups we had 26 women with histories of uneventful gestations and deliveries, 28 prepubertal girls, and 10 men. Anticomplementary activity was found in 19 (38%) of the 50 women with habitual abortions, in 4 (18%) of the 22 women with spontaneous abortions, in 7 (27%) of the 26 women with preeclampsia, and in 13 (22%) of 58 women with endometriosis. None of the patients who had had intrauterine deaths showed anticomplementary activity. Only 2 of 28 serum samples in the prepubertal-girls control group showed anticomplementary activity. Anticardiolipin antibody tests were done in all of the groups with enzyme-linked immunoadsorbent assay. The results of the serologic tests are shown in Table I.

Autoimmune abnormalities are thought to have a role in the pathogenesis of these disorders. There are two possible explanations for the anticomplementary activity seen. First, immune complexes or antigens such as cardiolipin can nonspecifically fixate complement and cause an anticomplementary effect. Second, patients with circulating immune complexes can also have autoantibodies against complement components.

Fetal hiccups and the umbilical ring

To the Editors: DeLee stated that fetal hiccups is "one of the most interesting phenomena of intrauterine life."1 To date, no clearly defined mechanism has explained this fetal behavior. Pillai and James² recently summarized that fetal hiccups become noticeable at about 24 weeks' gestation and diminish toward term. They described fetal diaphragmatic movements changing character and becoming more cyclic with increasing gestational age; they suggested that the fetal breathing center may be different from the mechanism that controls hiccups. The nerve impulses that may cause diaphragmatic contractions more plausibly originate by way of the umbilical ring. Cholinergic and adrenergic nerve terminals or end nests have been identified in the umbilical cord 20 cm out and concentrated toward the umbilical ring.^{3, 4} These nerve fibers run with the umbilical vein and sacral plexus to join the phrenic ganglion and celiac ganglion in proximity to the ductus venosus.5,6 These fibers run with the vagal trunks and eventually may interact with the phrenic nerve by way of the medulla and respiratory center. The phrenic nerve sends fibers to the pericardium, phrenic ganglion, sympathetic plexus, and hepatic plexus. Compression or stretch of the umbilical cord may lead to spasm of the ductus venosus7 or contractions of the . diaphragm via a similar reflex arc. As has been suggested by Ellison,3 the umbilical ring may function before birth rather than after birth and therefore is difficult to study once the infant is born. With this in mind it can also be theorized that the ductus arteriosus and foramen ovale are linked to the umbilical ring. Two cases of cord entanglement with fetal heart rate variables were noted in which the fetuses had daily hiccups near 36 weeks' gestation. Three to four episodes per day were recorded by the mothers for several weeks, along with fetal movements. The possibility of detecting cord entanglement or compression may be specific to persistent fetal hiccups.

Patients with preeclampsia may be insensitive to atrial natriuretic factor

To the Editors: August et al. are disturbed by the apparent discrepancy that increased blood atrial natriuretic factor is associated with relative hypovolemia in women with preeclampsia (August P, Lenz T, Ales KL, et al. Longitudinal study of the renin-angiotensinal dosterone system in hypertensive pregnant women: deviations related to the development of superimposed preeclampsia. Am J Obstet Gynecol. 1990;163:1612-21). For a solution, they challenge the hypovolemia concept, although it has been confirmed by many different studies with techniques other than Evans blue dye dilution. ^{1,2} Unfortunately, there is no currently approved technique for measuring plasma volume in pregnant women to re-prove the concept.

The apparent discrepancy between the high level of atrial natriuretic factor found in many studies of women with preeclampsia and their *apparent* hypovolemia can be explained by preeclampsia causing insensitivity to atrial natriuretic factor. Such an insensitivity could explain the hypertensive and edema symptoms of preeclampsia.⁵

1992 Roussel Prize. The ever-increasing importance of steroids in man, animal, and, perhaps in the future, plant health provided the incentive for the establishment of an International prize to support basic research in this area. The Roussel Prize, created in 1968 at the instigation of Prof. J. Mathieu, is awarded every two years to one or two chemists, biochemists, or physiologists whose work has been selected as the most outstanding by an international jury of distinguished scientists. The next Roussel Prize (\$40,000), which is scheduled in Autumn, 1992, is intended to reward one or more researchers for outstanding work on steroids and other squalenoids published before Dec. 31, 1991. The composition of the Jury for the year 1992 is as follows: President: Sir Derek Barton. Members: Professors M. Akhtar, J. Gorski, N. Ikekawa, J. Mathieu, Y. Mazur, and J. Sjövall. Candidates for the Prize may be of any nationality and from any laboratory. Nominations should be put forward by a person of high scientific standing, by means of the appropriate form and addressed to the President of the Jury or to the Secretariat of the Roussel Prize, before Jan. 1, 1992. Forms and any further information may be obtained from the Secretariat on request: Secretariat of the Roussel Prize, Institut Scientifique Roussel, 35 Boulevard des Invalides, 75007 Paris, France.

Generalist Obstetrician/Gynecologist Maternal/Fetal Medicine Subspecialist Gynecologic Oncologist Faculty Positions

The James H. Quillen College of Medicine of East Tennessee State University (ETSU) is seeking a board certified/eligible General Obstetrician/Gynecologist and a board certified/eligible Maternal/Fetal Medicine (Perinatology) subspecialist and a board certified/eligible Gynecologic Oncologist. These positions offer an excellent opportunity combining research, teaching and private practice with a faculty position at the Assistant/Associate Professor level. Salaries are very competitive and fringe benefits are excellent. The Medical School is located in the Tri-Cities area of Northeast Tennessee in a beautiful section of the Appalachians and within sight of the Blue Ridge Mountains. The area has excellent hunting, fishing, and camping with multiple ski resorts at your doorstep. The Tri-Cities combines good schools and rural living in a safe, beautiful environment. Yet, the medical referral base consists of 1.3 million people within a 50 mile radius of the Medical School. Send curriculum vitae to:

Frederick R. Jelovsek, M.D.
Professor and Chairman, Dept. OB/GYN
James H. Quillen College of Medicine
East Tennesee State University
P.O. Box 19570A
Johnson City, TN 37614-0002

ETSU is an AA/EO employer.

Laparoscopic Training For Advanced Operative Laparoscopy, Laparoscopic Hysterectomy and Operative Hysteroscopy

One, and two day courses directed by **Carmen Nezhat, M.D. & Farr Nezhat, M.D.** are conducted year round. Participants will benefit from the personal experience gained from more than 5,000 advanced operative endoscopy and video laseroscopy procedures.

Live surgery observation, will provide interactive discussion along with questions and answers. Hands on laboratory sessions provide didactic hands-on work with pelvic trainers, as well as operative techniques using the lasers, electro surgery, suturing and clips.

For further information, please contact Judy Leet at (404) 255-8778.

Group Health has shown that quality care at a reasonable price is not an impossible dream.

The New York Times, May 2, 1991

66 Group Health is my model for the future. 99

Arnold Relman, MD, retired editor, New England Journal of Medicine

Escalating malpractice costs make starting your own practice almost impossible. At Group Health, I earn a good salary and have time to enjoy it. 99

Ronald Helm, OB/GYN Tacoma Specialty Clinic

Group Health has been quietly revolutionizing health care since 1947. With the single premise that quality health care needn't be expensive, we've built one of the most respected managed care systems in America. Our physicians can concentrate their efforts on the practice of medicine without worrying about their next paycheck. This improves the relationship between doctor and patient, resulting in better health care.

Discover for yourself the future direction of health care. Call us toll-free at (800) 543-9323. Group Health is an equal opportunity employer.

UNIVERSITY OF WISCONSIN-MADISON MEDICAL SCHOOL

GYNECOLOGIC ONCOLOGIST

Albert Einstein Medical Center (AEMC), a 600+ bed tertiary care teaching hospital, is seeking a gynecologic oncologist to establish a service in the Division of Gynecologic Oncology. AEMC is a major referral center in north Philadelphia supporting numerous post-graduate medical education programs, including a fully accredited residency program in obstetrics and gynecology. The Department of Obstetrics and Gynecology has a longstanding tradition of excellence in healthcare delivery and supports a variety of clinical research and educational activities. The Division of Gynecologic Oncology serves as a tertiary referral center within the metropolitan Philadelphia area. This service is supported by a strong Department of Radiation Oncology and a newly established Cancer Center with a state of the art facility for outpatient chemotherapy. There is also major institutional support and emphasis in research with funds and laboratory space available for basic research. The responsibilities include education, patient care and research.

AEMC is a major affiliate of Temple University. Academic appointment is available for all full-time AEMC faculty. Highly competitive salary and very attractive fringe benefits are included. Candidates must be board certified or an active candidate for board certification in the Division of Gynecologic Oncology. If you are interested in this position or would like additional information about this unique opportunity, please write to Sze-ya Yeh, M.D., Chairman, Department of Obstetrics and Gynecology, Albert Einstein Medical Center, 5401 Old York Road, Klein #410, Philadelphia, PA 19141. Telephone (215) 456-6993, FAX (215) 456-6271.

OBSTETRICS & GYNECOLOGY

Obstetrician/Gynecologist needed to join a five physician department at a major regional multispecialty clinic in Billings, Montana. Clinic setting includes all specialties and is adjacent to an outstanding tertiary care referral hospital. Excellent opportunity for a top notch board eligible or board certified Obstetrican/Gynecologist looking for a challenging practice in a geographic area offering unlimited recreational potential. Those interested send CV to:

Ann B. Oglesby, M.B.A., M.D.
Medical Director
Billings Clinic
P.O. Box 35100
Billings, Montana 59107-5100

Physicians

The Department of Obstetrics and Gynecology is seeking physicians interested in:

- General Obstetrics and Gynecology
- Ambulatory Obstetrics and Gynecology

Candidates must be board certified or active candidates for certification. Academic rank commensurate with experience. Salary is competitive and a comprehensive fringe benefit package is provided.

Please send letter of interest and curriculum vitae to: David Acker, M.D., Chairman, Department of Obstetrics and Gynecology, Boston University School of Medicine, 80 East Concord Street, Boston, MA 02118.

The Boston University School of Medicine is an Equal Opportunity/Affirmative Action Employer

Boston University Medical Campus

BRIGHAM AND WOMEN'S

Urogynecologist

The Department of Obstetrics, Gynecology, and Reproductive Biology at Brigham and Women's Hospital, a major teaching hospital of Harvard Medical School, seeks a full-time Urogynecologist to direct a clinical and educational program in urogynecology.

Applicants must be Board-certified in Obstetrics and Gynecology, and must have advanced training and experience in the medical and surgical aspects of urogynecology.

Academic rank at Harvard Medical School will be commensurate with experience, training, and achievements.

Strong interpersonal skills and commitment to clinical care, research, and teaching are essential.

Send inquiry and curriculum vitae to:

Kenneth J. Ryan, M.D. Chairman, Department of OB/GYN Brigham and Women's Hospital 75 Francis Street, ASB1-3-073 Boston, MA 02115

The Brigham and Women's Hospital is an affirmative action, equal opportunity employer.

OB/GYN

Portland, Oregon.

Opportunity for a BE/BC, OB/ Gyn surgeon, with an established and busy multi-specialty medical clinic. Very strong primary care base for referrals: Salary quarantee and a bonus incentive: Benefits include professional liability insurance and a continuing education allotment. Send CV and three references to: Charles Darby, MD; Broadway Medical Clinic 4212 NE Broadway Portland, Oregon: 97213.

Gynecologist University of Pittsburgh School of Medicine

The Department of Obstetrics and Gynecology at the University of Pittsburgh is seeking a board-certified/eligible Gynecologist with a special interest in hysteroscopy and operative laparoscopy for a faculty position. Rank and salary commensurate with experience. Interested parties should send a curriculum vitae to:

> Marvin C. Rulin, M.D. Professor and Acting Chairman University of Pittsburgh School of Medicine Department of Obstetrics and Gynecology c/o Magee-Women's Hospital 300 Halket Street Pittsburgh, Pennsylvania 15213

An equal opportunity, affirmative action employer.

The Osler Institute Obstetrics and Gynecology Review Course

October 21-26, 1991 – Chicago [†]December 2-7, 1991 – Chicago

Now, your course for exams has practice tests and case-list review

OBJECTIVES

- Increase basic knowledge and clinical skills in ob-gyn
- Assist residents and fellows to organize their study
- Prepare exam candidates to take their examinations
- Provide practicing gynecologists with an update

METHODS

- HOME STUDY MATERIALS with questions and answers
- SEMINAR with projection slides and lecture-note syllabus
- LABORATORY with microscope and glass slides
- PRACTICE EXAMS with both oral and written sections

†Plus extra mock oral days December 8-9

"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities, but from people who are relatively unknown as well."*

Mycotic vulvovaginitis: A broad overview

1188

Benson J. Horowitz, MD

Hartford, Connecticut

Vulvovaginitis due to mycoses is on the rise in the United States. Precise identification of fungi is the cornerstone of accurate diagnostic and therapeutic decisions.

Mode of action of anti-Candida drugs: Focus on terconazole and other ergosterol biosynthesis inhibitors

1193

Hugo Vanden Bossche, ind Ir, and Patrick Marichal, ind Ir Beerse, Belgium

The fungitoxicity of azole antifungals originates from ergosterol depletion and accumulation of 14-methylsterols; that of the allylamines from inhibition of ergosterol synthesis and accumulation of squalene.

The in vitro activity of terconazole against yeasts: Its topical long-acting therapeutic efficacy in experimental vaginal candidiasis in rats

1200

Jan M. Van Cutsem, PhD

Beerse, Belgium

Short topical therapy schedules with terconazole in vaginal candidiasis in rats resulted in prolonged levels and was more efficacious than treatment with reference drugs.

Vulvovaginitis: The role of patient compliance in treatment success

1207

Sam A. Nixon, MD

Houston, Texas

Factors contributing to patient noncompliance in the treatment of vulvovaginitis and suggestions for optimizing compliance are explored.

Cytolytic vaginosis Leonard J. Cibley, MD, and Laurence J. Cibley, MD Boston, Massachusetts	1245
Cytolytic vaginosis is described, and diagnostic considerations and treatment are reviewed. The reasons for confusion between the diagnosis of cytolytic vaginosis and <i>Candida</i> are explored.	
Postpartum vaginal atrophy Peter M. Wisniewski, MD, and Edward J. Wilkinson, MD Philadelphia, Pennsylvania, and Gainesville, Florida	1249
Two hundred fifteen puerperas returning for a scheduled 4-week postpartum examination were studied to determine the clinical characteristics of vaginal atrophy.	
Vaginal cancer: The role of infectious and environmental factors Maria J. Merino, MD Bethesda, Maryland	1255
The role that infectious diseases, such as herpes simplex virus and human papillomavirus, and environmental factors play in the etiology of vaginal cancer is explored.	

The vaginal ecosystem

Per-Anders Mårdh, MD

Uppsala, Sweden

The ecology of vaginal flora is highly susceptible to numerous endogenous and exogenous influences. Possible mechanisms that might influence changes in the vaginal flora are microbial antibiosis, adhesion to the vaginal epithelial lining, e.g., availability of receptors, hormonal changes including physiologic alterations, disease states, drug therapy, sexual activity, and to a lesser extent, the immunologic status of the person. The role that these mechanisms may play in promoting vaginitis, vaginosis, and possibly pelvic inflammatory disease is explored. (AM J OBSTET GYNECOL 1991;165:1163-8.)

Key words: Vaginal flora, microbial ecology, vaginitis, vaginosis, etiology

During recent years the ecology of the vagina has been studied in both healthy women and those with pathologic conditions, such as bacterial vaginosis, candidiasis, and trichomoniasis. The microbial ecology of the vagina is a very delicate system that can be easily altered. Recent research has not only unveiled modes by which the vaginal flora and epithelial lining are changed by altered host-parasite interactions, but ways in which endogenous and exogenous factors such as hormonal therapy and other iatrogenic manipulations such as antibiotic therapy can affect the composition of this flora (Table I).

Vaginitis versus vaginosis

Vaginal infections, such as *Trichomonas vaginalis* and candidiasis, generally induce an inflammatory response in the vaginal wall, which is usually accompanied by an increased number of leukocytes in the vaginal fluid. Such an inflammatory response is the hallmark of "itis" conditions. An inflammatory response of the lower female genital tract may also accompany viral infections caused by herpes simplex and human papillomavirus.

Bacterial vaginosis (BV) accompanied by a vaginal flora change is not characterized by an inflammatory response. BV has alternatively been referred to as "nonspecific" vaginitis and vaginal bacteriosis. Lactobacillinduced cytolytic vaginosis (also called Döderlein cytolysis) is another form of vaginosis in which leukocytes are sparse.

Vaginal fluid

Vaginal fluid may contain various portions of cervical secretion, uterine, follicular, and peritoneal fluid, as

6/0/32673

Table I. Etiology of changes in vaginal flora

- Therapy with antibiotics, cytostatics, corticosteroids, antivirals, antifungals, and irradiation
- Vaginal douching
- Malformation and anatomic deformity after surgery and/or irradiation
- Cysts, hymen, polyps
- Immunosuppressive conditions, e.g., AIDS (less common)
- Hormonal changes from aging, use of oral contraceptives (less common), or therapy for disease
- Uncontrolled diabetes
- Foreign bodies, e.g., intrauterine device, or retained tampon or diaphragm
- Spermicides

AIDS, Acquired immunodeficiency syndrome.

well as exfoliated epithelial cells, bacteria, and bacterial products. Occasionally semen, contraceptive and hygiene products are added to the vaginal contents.

Composition of vaginal flora

"Normal" vaginal flora is usually dominated by lactobacilli. In contrast, the vaginal flora of women with BV consists of a combination of aerobic, facultatively anaerobic, oxygen-tolerant anaerobic, and strictly anaerobic bacteria. ^{1,2} BV in particular is associated with a high number of organisms, including *Gardnerella vaginalis* (the "clue" cell organism), *Bacteroides bivius* and other *Bacteroides* species, *Mycoplasma hominis*, and the newly named species *Mobiluncus mulieris* and *Mobiluncus curtisii*.

G. vaginalis can also be found in many healthy women, as can M. hominis. The latter organism occurs in approximately 15% to 30% of healthy, sexually active women. M. hominis and G. vaginalis can also be part of the vaginal flora in women with trichomoniasis or candidiasis, but the two Mobilincus species are rarely found in these two other conditions.

A strong case for classifying M. hominis, traditionally

considered a sexually-transmitted disease organism, as a BV-associated organism can be made based on, among others, the following observations: (1) It occurs in a high proportion of women with BV but only rarely in their sexual partners³; (2) it can be isolated from bladder urine, similar to G. vaginalis and M. curtisii, both BV-associated organisms³; (3) M. hominis can be isolated from extragenital abscesses in persons without signs of BV and can cause postpartum bacteremia like the latter two organisms; and (4) like G. vaginalis, it may occur in the intestinal flora of healthy men and women.

M. mulieris is almost exclusively found in the vagina of patients with BV. M. curtisii has been recovered from the upper genital tract in women with pelvic inflammatory disease.² In an ongoing Swedish study (the Afa study) of women attending a contraceptive clinic, 12.6% of 632 women had BV, the diagnosis of which was based on the presence of three of the four following criteria: (1) gray, homogenous vaginal discharge, (2) vaginal pH >4.7, (3) a positive amine test, or (4) a moderate or greater number of "clue" cells. This number increased to approximately 25% when less than a moderate number of "clue" cells were included.

Characteristic of Mobiluncus bacteria is corkscrew-like

motility, seen in approximately 16% of the women in the Afa study.

In contrast to *Mobiluncus* species, *Bacteroides* species, anaerobic gram-positive cocci, and fusobacteria are found with equal frequency in BV, trichomoniasis, and candidiasis.¹

Campylobacter fetus, subspecies venerealis, is an organism relatively recently discovered in the vaginas of healthy women and those with BV. It is known as a cause of abortion in animals but not in women.

The intestinal tract as probable microbial reservoir

It is currently believed that the intestinal tract is the reservoir for organisms found in the vagina of women with BV. BV-associated organisms, such as *Mobiluncus* species, can be found in the rectum of women with BV as often as those without BV. They are also isolated from the intestinal tract of men without BV-affected partners and in fecal specimens of children.

Mechanisms involved in vaginal flora alterations

Hormonal factors probably play a role in the pathogenesis of BV, because it is a condition that affects only women in reproductive ages. However, oral contraceptives do not affect its incidence. One other hypothesis is that BV is the result of altered vaginal antibiosis or antagonism between organisms occurring in the vagina.

Lactobacilli decrease the vaginal pH through production of acidic products, thereby making the vagina inhospitable to some bacterial species. The efficiency of antibiosis is influenced by the pH. However, the presence of certain anaerobic lactobacilli in the vagina of women with BV does not afford the same protective antibiosis that facultatively anaerobic lactobacilli do. It is now believed that the antibiosis exhibited by some lactobacilli may, among other mechanisms, be from endopeptidase production as indicated by in vitro studies. The vaginal flora of lactobacilli, which is dominated by Lactobacillus acidophilus (Table II), is itself regulated by lactocins, which are bacteriocin-like products of lactobacilli and directed against lactobacilli.

Another mechanism for regulating the ecology of the vagina may be the production of hydrogen peroxide

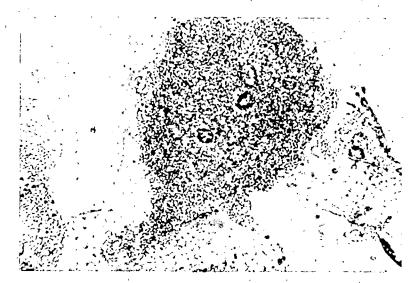

Fig. 1. Typical "clue" cell of bacterial vaginosis, Gardnerella vaginalis attached to vaginal epithelial

(H₂O₂) by lactobacilli, because healthy women are more likely to have H₂O₂-producing lactobacilli than women with BV (Table III).

Candicidin, like bacteriocins and lactocins, may be involved in the regulation of the occurrence of yeast fungi in the vaginal flora.

Receptor availability and binding factors

Alterations in the composition of the vaginal flora that facilitate bacterial colonization may also be related to changes in the availability of receptors on eukaryotic cells of the vaginal epithelial lining. It is likely that physiologic changes of the vaginal milieu are often the result of endogenous rather than exogenous factors. The chemical nature of receptors for G. vaginalis, Candida albicans, and the two Mobiluncus species are of carbohydrate nature.

Whether there is a change in the glycocalyx covering of the epithelial cells or changed exposure of the receptor sites that facilitates bacterial adherence is not yet clear. Increased pH levels are generally associated with an increased ability of bacterial binding to eukaryotic cells; it is not known whether the change in pH facilitates a change in vaginal flora or vice versa.

One striking feature of BV is the occurrence of "clue" cells,7 that is, exfoliated vaginal epithelial cells covered by G. vaginalis bacteria (Fig. 1). These cells could also have been referred to as "glue" cells because the bacteria appear to be glued to the epithelial cells. Likewise, recent microbiologic studies have revealed that the curved rod of Mobiluncus (Fig. 2) attaches to vaginal epithelial cells, creating "comma cells."

Among other possible factors that may be involved in bacteria persisting in the vagina are mucus including glycoproteins, lactoferrin, and metal ions, such as zinc and magnesium. Lysozyme, which is found in most

body fluids and is primarily active against gram-positive organisms, interferes with the ability of bacteria but not with chlamydiae to form inclusions in tissue cell cultures.

Fibronectin, a glycoprotein found in connective tissue and free in some body fluids, including vaginal fluid, may also play a role in the persistence in the vagina of organisms such as staphylococci, streptococci, and lactobacilli.

Lactobacilli and other bacteria may be randomly distributed on the surface of epithelial cells, which should not be confused with bacteria attached to cell surface receptors or glycocalyx components. There might be receptor analogues in the glycocalyx to which bacteria may associate.

Hormonal changes

It is well known that throughout a woman's life, physiologic hormonal changes alter the vaginal flora. One of the prime examples is pregnancy, during which the vaginal pH generally becomes more acidic. Pregnancy increases the risk of vaginal candidiasis. This fact suggests that pH alterations and cellular changes may play a role in regulating overgrowth of Candida. A hormonal influence is also suggested to explain cytolytic vaginosis, which generally occurs in young girls with an abundant overgrowth of lactobacilli and lysis of epithelial white blood cells.8

Oral contraceptives or other steroid treatment can also theoretically alter the vaginal flora. Modern oral contraceptives have generally little influence on the vaginal flora. One observation of interest in this conjecture is that there is evidence of estrogen receptors on C. albicans organisms. However, its role in regulating the occurrence of this yeast fungi in the vagina has not been borne out by clinical experience.

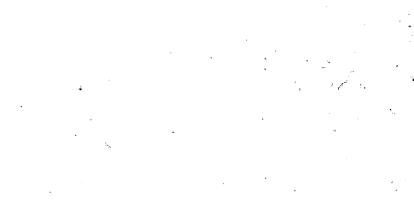

Fig. 2. Typical "comma"-shaped cell seen in bacterial vaginosis caused by the curved rod-shaped *Mobiliuncus* species.

Table IV. Number of lifetime sexual partners of women with and without signs of BV*

	. 0

*Defined as fulfilling three of four of: vaginal pH >4.7, positive amine test, gray homogenous discharge, and moderate to high number of "clue" cells.

Vaginal contraceptives that may influence the vaginal ecology

The vaginal flora can be altered by prolonged retention of a diaphragm and tampon and by vaginal douching. Moreover, the use of an intrauterine device, particularly one with a "tail" extending through the cervical os, increases the risk of pelvic inflammatory disease in women with BV flora. 9, 10

Spermicides containing nonoxynol-9 may affect the vaginal flora. Their use in the form of a cream or in a contraceptive sponge is associated with an increased resistance to some sexually transmitted diseases, such as gonorrhea, chlamydial infection, and human immunodeficiency virus infections.^{11, 12} An in vitro effect of spermicides against the agents causing these infections can be shown.

Disease states

Some generalized disease states, such as poorly controlled diabetes mellitus, appear to predispose women to vaginal candidiasis.

Although an increased incidence of oral and intestinal candidiasis is generally more common in patients with acquired immunodeficiency syndrome than in comparison groups, this does not seem to hold true for the genital tract.

Drug therapy

When the endogenous vaginal flora are eradicated by broad-spectrum antibiotics, such as during the treatment of sexually transmitted diseases or respiratory tract infections, overgrowth of *Candida* (generally *C. albicans*) can be anticipated in a subpopulation of women. Long-term therapy, however, is more likely to cause this type of overgrowth than short-term treatment. Likewise, long-term cytostatic, corticosteroid, antiviral, and antifungal drug therapy can also alter the vaginal flora, thus promoting vaginitis.

The role of the male sex partner

Although the male sex partner plays an essential role in the pathogenesis of sexually transmitted disease-causing cervicitis and in vaginal infections such as in trichomoniasis, herpes, and genital warts, the role of the partner in the pathogenesis in BV and candidiasis is less certain.

Colonization with BV-associated bacteria is no more frequent in the urethra of sex partners of women with BV than it is in the sex partners of women without BV.¹³ In uncircumcised male partners of women with BV, a higher colonization rate is found in the sulcus of the glans penis than in the urethra.

In a study of 100 men at a sexually transmitted disease clinic, M. curtisii and G. vaginalis were isolated in approximately 10% of patients, whereas M. mulieris was never recovered.14 In another study, similar isolation rates were found in male partners of women with BV, but only 5% of men, independent of whether their sex partners had BV, were colonized rectally with BV-associated bacteria.11 These observations argue against sexual transfer being important and that concomitant treatment of women with BV and their male sex partners with metronidazole has any major impact on BV.14 Although one study found that the use of condoms may normalize the vaginal flora in women with BV,15 for the most part, the evidence suggests that BV is not a sexually transmitted disease. This argument is strengthened by the recent finding that the prevalence of BV does not increase by an increasing number of lifetime sexual partners (Table IV).

In women with vaginal candidiasis, male partners, particularly uncircumcised ones, are often colonized by C. albicans. A small proportion of these men develop balanitis. In isolated cases, concomitant treatment of both partners may be useful, and use of condoms during intercourse may protect women from recurrent bouts of candidiasis. Moreover, yeast colonization in the male partner can also disappear once the woman alone has been treated. Yet, sexual transmission of candidiasis resulting in clinical disease is by no means commonplace.

Local immune defense

The secretory antibody defense mechanisms, which agglutinate bacteria, do not seem to be highly efficient in preventing BV and other types of changes in the vaginal flora. This is possibly because of bacterial proteinases produced by vaginal colonizers, many of which have the ability to break down IgA-1.

The role of IgG antibodies and complement factors in BV and candidiasis in microbial cell lysis has not been well studied, but it appears that IgG antibody opsonization of bacteria does not occur very efficiently in vaginal fluid. The level of vaginal fluid complement is only 11% of that in serum. Moreover, the effect of complement may be inhibited by semen, which also has additional inhibitory effects on the immune system in the genital tract. The inefficiency of the immune system to hinder infections of the lower genital tract may be exemplified by trichomoniasis. Although humoral IgM, IgG, and IgA antibodies to T vaginalis and IgG and IgA antibodies can be detected in vaginal fluid, these antibodies do not seem to play any protective role in this type of vaginitis. A T-cell response can also be demonstrated in trichomoniasis, but without any great effectiveness in protecting the individual from developing this condition.

Long-term consequences of vaginitis and vaginosis

Organisms that colonize the vagina in women with BV, in particular, organisms belonging to the genus Mobiluncus, can spread to the upper genital tract and be associated with pelvic inflammatory disease, that is, endometritis or salpingitis.2 It is also a well-established fact that infections of the lower genital tract are correlated with dysplasia and cervical neoplasia. The most striking data are for certain types of human papillomavirus, which has been reported to be associated with neoplastic cervical changes.16 Although similar observations have been made for M. hominis¹⁷ and Mobiluncus species, but few if any of these studies claiming an association between human papillomavirus and neoplasia have controlled for the vast number of organisms present in the genital tract of carriers of human papillomavirus. The oncogenic potential of nitrosamines, which are produced by certain vaginal bacteria inhabitants of women with BV, has also been brought forward.

Finally, the possibility that vaginitis or vaginosis may increase the possibility of acquiring or transmitting acquired immunodeficiency syndrome needs to be studied. Such an association has already been demonstrated for genital lesions caused by Hemophilus ducreyi18 and by C. trachomatis.19

Epidemiology of vaginitis

Howard L. Kent, MD

Philadelphia, Pennsylvania

Vaginitis is one of the most common problems in clinical medicine, and it is the reason cited most often for visits to obstetricians and gynecologists. This article reviews the epidemiology in the United States and Scandinavia for the three major causes of vaginitis: candidiasis, trichomoniasis, and bacterial vaginosis. The incidence of candidiasis has increased dramatically during the past decade, with an increase in the percentage of non-albicans Candida strains. However, in Scandinavia the incidence of candidiasis has been relatively stable, between 10% and 30%, during the past 5 years. The incidence of *Trichomonas* has decreased dramatically in both the United States and Scandinavia during the past 15 years, partly attributable to the advent of metronidazole. In the United States bacterial vaginosis continues to be the leading variety of vaginal infection, affecting a broader spectrum of women than gonorrhea. The prevalence of bacterial vaginosis in Scandinavia is about 30%, and this percentage increases with age according to studies of patients at sexually transmitted disease clinics. (AM J OBSTET GYNECOL 1991;165:1168-76.)

Key words: Vaginitis, vulvovaginal candidiasis, trichomoniasis, bacterial vaginosis

In the recent past, the problem of vaginitis has all too often been ignored by the medical community or regarded merely as a minor annoyance to women. Perhaps the late Herman Gardner put it most eloquently when he stated, "Vaginitis must cause more unhappiness on earth than any other gynecologic disease. In addition to the many physical and emotional problems associated with vaginitis, the economic loss involved is of astronomic proportions."

From the Department of Obstetrics and Gynecology, Jefferson Medical College of Thomas Jefferson University.

6/0/32467

When discussing the problem of acute vaginitis, we must be aware of the following facts:

- Vaginitis is one of the most common problems in clinical medicine.
- Vaginitis accounts for more than 10 million office visits each year.^{2, 3}
- Vaginitis is the most common reason for a patient to visit her obstetrician-gynecologist.
- Vaginitis is found in 28% of women attending sexually transmitted disease (STD) clinics.
- Candidiasis is the second most frequent vaginal infection in the United States and the primary vaginal infection in Europe.
- Twenty-five percent to 40% of women with an

overgrowth of vaginal Candida are asymptomatic carriers.

- Mild leukorrhea resulting from Candida may be dismissed as a physiologic condition.
- Vaginitis may produce symptoms similar to urinary tract infections (dysuria).
- Vaginal discharge is among the top 25 reasons for physician consultations by patients.

Sexually active women are at increased risk for vaginitis because the presence of semen in the vagina may raise the pH and thereby allow for a proliferation of pathogenic anaerobic bacteria. It is well known that the risk of vaginitis and all STDs is increased in women with multiple sex partners.

This discussion will concentrate on the three conditions that are the most common causes of infective vaginitis—candidiasis, trichomoniasis, and bacterial vaginosis (BV). It should be noted, however, that more obscure infective agents can also cause vulvovaginitis. Some of these include various gram-positive and gramnegative microorganisms, Mobiluncus species, Chlamydia trachomatis, herpes simplex virus, human papillomavirus, Enterobius vermicularis (pinworm), and Giardia lamblia.

In addition to infective causes, allergic or chemically irritative vaginitis can be caused by a great number of substances in our environment. In these situations patients demonstrate long-standing symptoms or recurrent symptoms of vaginal irritation with no demonstrable cause of infection. A detailed history is necessary to disclose the offending substance. The patient should be asked to compile a list of all materials that have come in contact with her perineum. Common materials that exhibit potential irritant effects include deodorants, soaps, vaginal sprays, tampons or pads, colored or perfumed toilet tissue, bubble bath, laundry detergents (especially those with enzymes), fabric softeners, frequent minipad use, tight-fitting synthetic underwear, swimming pools or hot tubs, and vaginal contraceptives or condoms.4

To understand the epidemiology of vaginitis, we must first discuss some basic definitions. Epidemiology is a branch of medical science that deals with the incidence, distribution, and control of disease in a population. It is the sum of factors controlling the presence or absence of a disease or pathology.5

Epidemiology is concerned with patterns of disease occurrence in human populations and the factors that influence these patterns. The epidemiologist is interested in disease as it relates to time, place, and person. To this end, epidemiologists may attempt to determine if a disease's characteristics are changing over time or if it is found in a specific geographic locale. The personal characteristics regarding the demography, biology, socioeconomic factors, individual habits and attributes, and heritable traits associated with disease are also pursued.6

The frequency with which a disease is encountered can be expressed by the terms prevalence and incidence. These two terms are different and are not interchangeable. Prevalence defines the number of cases of a disease process present in the population at risk at a specific time. The populaton at risk can be the entire population of an area but is usually limited to those persons who have been tested for the specific condition. Incidence is defined as the number of new cases that develop in a given population during a defined time period.7,8

Vaginitis is an ancient disease and was described by Hippocrates. In the first century AD, Soranus made the following reference to vaginal discharge: "According to Asclepiades and some others there are two different kinds of flux (for one kind is red, the other is watery and white), whereas according to Demetrius the differences lie in color and action.... In action one kind of flux is inactive and causes neither irritation nor pain, whereas the other kind causes irritation and erosion and brings on a painful sensation at the time of discharge."9

Epidemiology of candidiasis

In this century, the incidence of vaginal candidiasis has increased dramatically. In England the incidence has varied between 28% and 37%. According to Bingham, 10 an infectious disease expert who annually monitors the number of cases of genital yeast infections at STD clinics, between 1971 and 1981 there has been a 42% increase in the incidence of vaginal candidiasis (Fig. 1).

In the United States, mycotic vaginitis has also increased significantly. Between 1980 and 1990, the incidence has nearly doubled. This is associated with an 80% increase in the number of prescriptions written to treat yeast infections in the same time span. It is also significant that the percentage of non-albicans Candida infections is also rising dramatically,1,11

In the 1970s, the incidence of non-albicans vaginal infections was approximately 5% to 10%, and in the 1980s it increased from 15% to 25%. A study in the 1980s involving 728 isolates from women with vaginal candidiasis showed a prevalance of 21.3% nonalbicans species (Table I). In evaluating these data, no specific relationship was discernible between the presence of predisposing factors or the use of previous medication and the occurrence of non-albicans species.

Speciation of these non-albicans species reveals that between 1963 and 1987 (15 studies), the incidence of C. tropicalis increased from 1.3% in the 1970s to 8.2% in the 1980s. C. glabrata also increased over this same

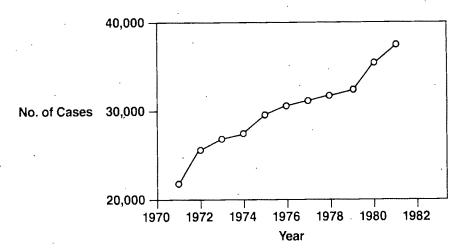

Fig. 1. Evolution of vaginal candidiasis in the United Kingdom; cases collected from STD clinics only.

Table I. Incidence of non-albicans Candida vaginitis in the 1970s and 1980s*

Species	1970s (9 studies)	1980s (7 studies)
C. albicans	1143 (90.1%)	573 (78.7%)
Non-albicans	126 (9.9%)	155 (21.3%)
Total isolates	1269	728

^{*}Survey included only patients with signs and symptoms of vaginitis.

time interval from 4.5% to 6.7% of specific yeast isolates. It is apparent that during these 3 decades, there has been a shift toward increasing percentages of non-albicans infections.

Epidemiology of trichomoniasis

In the United States, Joseph G. Lossick has recently published a report on the epidemiology of vaginal trichomoniasis. In his paper Lossick (personal communication) cites preliminary information on the incidence of *Trichomonas* vaginitis and BV in one STD clinic population.

Vaginitis data were obtained from the National Disease and Therapeutic Index survey, which is composed of a nationally stratified random sample of office-based practice physicians in 19 primary care specialties. More than 2100 physicians report on patient diagnoses and drug use (by individual case report) during a 20-day period each quarter. Physician visit frequency estimates are then extrapolated from these data. In this way crude estimates of the frequency and distribution of diseases seen in the office-based medical setting are developed. These data are particularly relevant for infections ordinarily treated on an outpatient basis, such as trichomoniasis. As with other stratified random sampling schemes, these data are sometimes characterized

by broad confidence intervals or error rates typically associated with population estimates that are developed from a small number of disease occurrences. Based on the size of the visit, volume estimate error rates vary. Statistical procedures have been used to answer questions concering the precision of case definitions and the consistency of the National Disease and Therapeutic Index data over time. The primary purpose was to identify patterns and trends rather than specific disease frequencies.¹²

Patterns of physician visits for *Trichomonas* vaginitis during the 22-year period from 1966 to 1988 show that there has been an approximate 40% decrease during this time span (Fig. 2). These data correlate well with worldwide trends in the occurrence of *Trichomonas*.

Using frequency of physician visits as a reference point, when physician visits are separated into specific geographic regions (West, South, Midwest, and Northeast), one can see differences and similarities in each region. The distribution of infection appears to vary by region, with the highest frequency occurring in the South and the lowest in the West. All areas of the United States have demonstrated similar decreases in morbidity except in the southern states, where the decrease began approximately 5 years later (1980) and has been only half of that seen in other geographic areas (Fig. 3).¹³

Similarly, data on first physician visit demonstrate a higher frequency of visits for black women with *Trichomonas* vaginitis, which is consistent with worldwide data. Fig. 4 shows the estimated U.S. race-specific first visit rate for *Trichomonas* per 100,000 women between 1982 and 1987 (race data were not available before 1982). The data suggest that black women sought treatment for *Trichomonas vaginalis* infections about four times more frequently than did white women. During the study period, first physician visits for

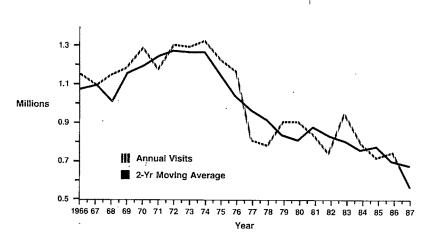

Fig. 2. Physician visits for trichomonal vaginitis, National Disease and Therapeutic Index survey data.

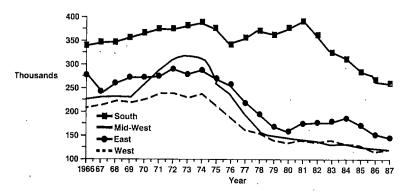

Fig. 3. Physician visits for trichomonal vaginitis by geographic region, United States, National Disease and Therapeutic Index survey data.

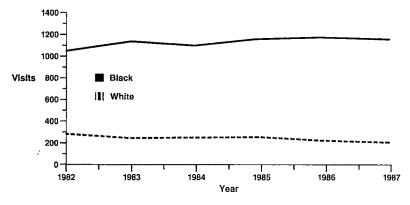

Fig. 4. First trichomonal physician visit rates/100,000, National Disease and Therapeutic Index survey data.

trichomoniasis increased slightly for black women, whereas there was a decrease in visits by white women. Although a higher proportion of black women sought treatment for trichomoniasis, almost two thirds of all physician visits for this infection occurred in white females (Fig. 5). Targeting resources totally to a minority population with a high prevalence may be ineffective, because if all T. vaginalis infections in black females

were eradicated, the largest proportion of infected women would still remain (Fig. 5).12,14

Increasing age and maturity does not decrease a woman's risk of acquiring trichomoniasis; however, the National Disease and Therapeutic Index data show that this infection is predominantly a disease of young women. Fig. 6 shows the age distribution of first physician visits for Trichomonas, and about two thirds of

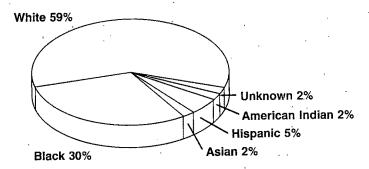

Fig. 5. Racial distribution of first visits for trichomonal vaginitis infections, United States, National Disease and Therapeutic Index survey data.

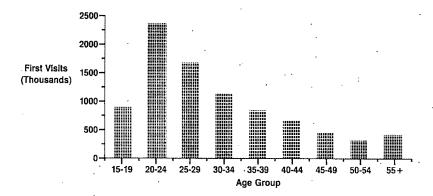

Fig. 6. Age group distribution of first physician visits for trichomonal vaginitis from 1982 to 1987, United States, National Disease and Therapeutic Index survey data.

these visits were made by women under 30 years of age.

Cases of *Trichomonas* vaginitis are distributed widely throughout the continental United States, but there is a higher incidence in the South. Although frequency of first visit is highest in black women and age does not play a role in the patient's susceptibility to *Trichomonas*, most of the infections occur in young white women. However, overall a significant decrease has occurred in the incidence of *Trichomonas* during the past 15 years.

Epidemiology of BV

Lossick developed data on the incidence of BV from patients attending an STD clinic in Columbus, Ohio. The study population consisted of 10,500 women who attended this clinic between 1985 and 1987. BV was diagnosed solely from clinical findings based on established criteria (signs and symptoms, vaginal pH, wet preparation findings, etc.). Because STD clinic populations are not typical for the average female population with venereal disease, these data do not indicate a quantification of risk factors. Therefore epidemiologic characteristics of BV were compared with those of gonorrhea in the same patient population. Total cases include 2000 patients with BV and 2500 with gonorrhea.^{15, 16}

At the STD clinic, frequencies of BV, C. trachomatis, Neisseria gonorrhoeae, and T. vaginalis infections were 17.7%, 25.3%, 24.4%, and 24.9%, respectively. The age distribution of BV was significantly different from that seen in gonorrhea (Fig. 7). In contrast to gonorrhea, which showed an inverse relationship between age and infection rates, the frequencies of BV varied little by age except at the extremes. In sharp contrast to gonorrhea, which was most prevalent in black women, there was no racial prevalence in BV (Fig. 8).

Women with BV were more likely to have had a history of STD: 54% of women with BV reported at least one prior STD versus 36% of women with gonorrhea. Women with gonorrhea came more frequently from inner-city areas, whereas there was no geographic clustering of patients with BV (Fig. 9). Women with gonorrhea were more likely to use oral contraceptives or no contraception, whereas women with BV were more likely to use intrauterine devices, condoms, and diaphragms (Fig. 10).

The descriptive epidemiology of BV in this study differs significantly from that of gonorrhea. Clinical patients with BV were more widely distributed geographically than those with gonorrhea and were neither racially nor age group clustered. Although BV can com-

monly affect women with gonorrhea, these data indicate that BV affects a much broader spectrum of women than does gonorrhea and in all probability affects women not at high risk for gonorrhea infection.

Epidemiology in Scandinavia

Moi has completed a recent evaluation of the incidence of vaginitis in the Scandinavian countries. As with other countries of the world. vaginitis caused by *Candida, Trichomonas*, or anaerobic organisms is not a reportable disease, and therefore other evaluations must be used to develop some sense of frequency. Prevalence figures are only available from a limited number of surveys compiled from data from STD clinics.¹⁷

In the discussion of trichomoniasis, Moi notes that until 20 to 30 years ago, the occurrence of *T. vaginalis* in specific subpopulations of the Scandinavian countries were correlated with sexual promiscuity. Metronidazole was registered in Sweden in 1957 and within 2 years in the other Scandinavian countries. Since then, the natural course of the disease has been altered through the use of metronidazole, and there has been a steady decline in the incidence of cases.

In contrast to the work of Lossick, Moi states that in

a 1969 study by Bjerre, Papanicolaou smears were evaluated for the presence of *Trichomonas*, and increasing prevalence of *Trichomonas* was found with the increased age of the patient. Teenagers were infected in 3% of cases, whereas menopausal women were infected 18% of the time, with a mean incidence of 9.6%. In other Papanicolaou smear surveys from Sweden and Denmark done during the 1960s, the prevalence of *T. vaginalis* varied from 6.5% to 28%. The highest incidence was found in the port city of Frederiksberg, a part of metropolitan Copenhagen. This high yield was attributed to a more precise evaluation of the Papanicolaou smears and also to a more cosmopolitan population in that area.

In a study from Ostergotland, a positive correlation was reported between the finding of *Trichomonas* in Papanicolaou smears and the occurrence of cervical dysplasia. Thirty percent of women with cancer in situ of the cervix had associated trichomonal infection, whereas only 7.4% of the entire group had *Trichomonas* present. The presence of *Trichomonas* in Copenhagen has decreased from 21% in 1977 to 0.4% in 1988.

In a study from the town of Malmö, Sweden, the number of newly diagnosed cases of trichomoniasis

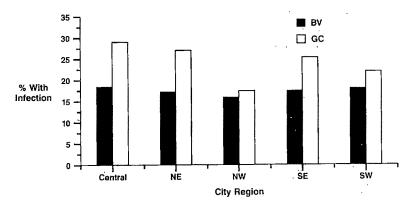

Fig. 9. Distribution of BV and gonorrhea cases by city region. GC, Gonorrhea. (From Lossick JG. Rev Infect Dis 1990;12[suppl 6]:665-81, by permission of The University of Chicago.)

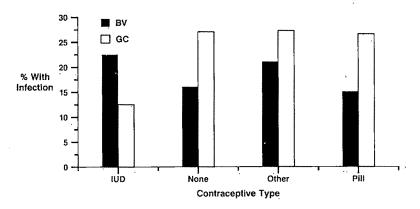

Fig. 10. Contraceptive practices and the frequencies of BV and gonorrhea. GC, Gonorrhea. (From Lossick [G. Rev Infect Dis 1990;12[suppl 6]:665-81, by permission of The University of Chicago.)

from 1975 to 1980 remained at approximately 100 per year. During that same span, the yearly number of cases of gonorrhea decreased from 550 to 300. By 1985 gonorrhea had decreased to 100 cases per year, a prevalence of 19%, whereas trichomoniasis had decreased 5 to 28 cases, a prevalence of 5%. In 1988, 8 cases of trichomoniasis and 18 cases of gonorrhea were diagnosed, a prevalence of 1% and 2%, respectively.¹⁷

In Gothenberg on the west coast of Sweden, there was a 1% to 2% prevalence of trichomoniasis in the STD clinic from 1986 to 1988. Gonorrhea was virtually unseen, with a prevalence of less than 0.5% of new patients.

In Sweden, most causes of trichomoniasis are now seen in women 30 years of age or older. During the past 5 years, about 20% of all new cases of *Trichomonas* were reported as arising during holiday trips to the Mediterranean area.

In a report from the Swedish State Bacteriologic Laboratory in 1989, 1300 cases of gonorrhea were reported in Sweden during calendar year 1988, with a monthly incidence in 1989 of less than 100 cases; trichomoniasis showed a similar marked decline in prevalence. Specific

reasons for the decline in gonorrhea and trichomoniasis in Sweden are believed to hinge on the fact that both these STDs tend to affect the same patients. Prophylactic partner treatment of trichomoniasis without examination has been practiced for more than 20 years in Sweden. Moi¹⁷ postulates that the more frequent use of condoms and decreased promiscuity because of concern about acquired immunodeficiency syndrome are also significant factors in the decrease in *Trichomonas*.

Candidal vulvovaginitis

In the evaluation of women without symptoms in Scandinavia, Moi reports a 15% incidence of candidal carriage. No significant changes in the incidence of vulvovaginal candidiasis have been reported from the Scandinavian countries. In the Oslo STD clinic, vaginal culture for yeast is taken from all women irrespective of symptoms, and for the past 5 years the prevalence has been 28% to 30%. This includes mycotic infections that occur after broad-spectrum antibiotic treatment.

In a study from Stockholm in 1975, the prevalence of *Candida albicans* as determined by culture was 17.3% (233/1347 women) in women attending an STD clinic.

Forty-five of these women had no symptoms of disease. The prevalence of symptoms of candidal vulvovaginitis was 13.4%.

Bacterial vaginosis

In 1986, 1100 of 3500 women attending the STD clinic in Copenhagen had BV, with a prevalence of 30%. The diagnosis was made by clinical criteria with confirmation on wet mount preparations. In Uppsala, Sweden, in 1984, a similar incidence of 33% was reported from the STD clinic in Orebro.

In a Swedish survey of 8000 Papanicolaou smears conducted by Larson,17 the prevalence of BV was 15%. The smears were from women 30 years of age or older attending a cancer screening program in 1976. It was concluded that there was a positive correlation between BV and cervical dysplasia. In both BV and trichomoniasis, foul-smelling amines are produced by the action of anaerobes, and it is believed that some of these amines are carcinogenic cofactors in the production of cervical carcinoma.

In a study of 518 women applying for legal abortion, 170 (33%) had BV.

A recent analysis of women attending an STD clinic in Orebro, Sweden, has been completed (1984 to 1988), in which 3800 new visits were compiled. Seventy percent of the women were 24 years old or younger, and most were serially monogamous with stable spousal relationships. Using established clinical criteria, the mean prevalence of BV was 26%. This prevalence increased significantly with age, with each 5-year group having about a 5% higher prevalence of BV. Twenty percent of the teenagers had BV, whereas more than 40% of the women in the 40- to 45-year-old group had positive findings.17 There was a positive correlation between BV and chlamydial infection, whereas there was a negative correlation between vulvovaginal candidiasis and human papillomavirus infection.

The correlation between BV and various contraceptives was calculated in the younger age group (below age 25 years). There was a significant negative correlation between the use of oral contraceptives and BV. There was also a negative correlation between the use of barrier methods of contraception and BV but a positive correlation with an intrauterine device in situ. Oral contraceptives have a protective effect against Trichomonas, possibly as a result of the acidic Lactobacillus predominant in vaginal flora. This same effect could explain the protective effect that oral contraceptives confer on BV.

Summary

Both trichomoniasis and gonorrhea have shown a marked decrease during the past decade in Scandinavia. The prevalance of trichomoniasis is now reported as less than 1% in STD clinics. The prevalence of vulvovaginal candidiasis in STDs in Scandinavia has remained relatively stable at 10% to 30% during the past 5 years without any obvious change in trend. The prevalence of BV in several STD clinic populations has been reported to vary between 15% and 33%.

It is obvious that no studies can document the actual specific incidences of vaginitis because vaginitis is not a reportable disease, and attempts to arrive at a precise figure can only be approximated by peripheral evaluations.

Studies that involve registrants of STD clinic populations are obviously flawed, because only a small spectrum of the entire female population attends these clinics, and those who do are more likely to be carriers of vaginal pathogens.

Studies on the Scandinavian population have been well done because of the meticulous record-keeping in the state-controlled medical system, but the incidence of disease is that of a homogenous temperate climate population. Data suggest that the incidence of vaginitis is greater in the more humid subtropical countries, where both infection and transmission of the disease vectors are facilitated.

Studies on the incidence of vaginitis in the United States are based on a very small sampling of patients but indicate a higher incidence of vaginitis in the southern states compared with those in the North and the West.

From a worldwide perspective, it is evident that the number of cases of trichomoniasis has decreased during the past 15 to 20 years, largely as a result of better diagnosis and the use of metronidazole as a systemic medication. Although there has been documentation of metronidazole-resistant trichomonads since 1963, it seems that resistance is not all or none and that by increasing the time exposure and dosage of metronidazole, the vast majority of trichomonads can be eradicated. With several new anti-Trichomonas drugs in clinical trials, it seems that Trichomonas will continue on its downward spiral.

In contrast, the number of new cases of candidal vaginitis has been on the increase during the past decade, and this problem has been compounded by the appearance of an increasing percentage of non-albicans species. This has led to the development of candidal vulvovaginitis that is more resistant to the usual drugs of choice. This situation will require more elaborate strategies in the development of more efficient drugs and the manipulation of the immune response to bring about a decrease in the number of cases of candidal vaginitis.

BV continues to be the leading variety of vaginal infection in the United States. With an increased understanding of the diverse flora in the vagina and the interplay of many species in the production of this disease entity, it is hoped that this problem will soon be more readily treated and controlled.

Vulvitis and vulvovaginitis: Cutaneous considerations

Marilynne McKay, MD

Atlanta, Georgia

Vulvar dermatoses (previously dystrophies) include psoriasis, allergic or irritant reactions, lichen sclerosus, lichen simplex chronicus, lichen planus, and tinea. Some of these have bullous or erosive forms, but they differ from the immune-mediated vesiculobullous disease group, which includes vulvar pemphigus, benign familial pemphigus, pemphigoid, linear IgA disease, and dermatitis herpetiformis. Vulvar ulcers can occur in dermatoses resulting from systemic disease (Behçet's syndrome, lupus, pellagra, and Reiter's disease) or malignancies resembling dermatoses (extramammary Paget's disease, squamous cell carcinoma, and vulvar intraepithelial neoplasia). Many vulvar dermatoses itch or burn. Vulvodynia occurs with irritant and allergic dermatitis, vulvar dermatoses, complications of steroid use, candidiasis, papillomatosis, vestibulitis, or essential (dysesthetic) vulvodynia. Diagnostic tests (potassium hydroxide, cultures, and biopsy) should establish the diagnosis and therapy should be specific. Few skin diseases are curable but all are treatable; effective management is defined by whether a medication reliably controls outbreaks or symptoms when it is used. Patience is recommended, because treatment may take weeks or months. (AM J OBSTET GYNECOL 1991;165:1176-82.)

Key words: Vulvar dermatoses, vulvodynia, psoriasis, lichen sclerosus, lichen simplex chronicus, lichen planus, tinea, vulvar ulcers

Vulvar itching and burning are not always symptoms of vaginitis; they are also typical of dermatitis or primary skin diseases. Patients who believe they have vaginitis often self-treat with medications that can complicate subsequent correct diagnosis and therapy. This article reviews the spectrum and differential diagnosis of vulvar cutaneous disease and symptoms (pruritus vulvae and vulvodynia). Principles of diagnosis and therapy include finer points and pitfalls of dermatologic management.

The term "dystrophy," which was once part of the

International Society for the Study of Vulvar Disease classification scheme for cutaneous vulvar disorders (atrophic, hyperplastic, and mixed), has now been replaced by "dermatoses." The new categories are as follows: (1) lichen sclerosus, (2) other dermatoses, and (3) squamous cell hyperplasia (formerly hyperplastic dystrophy or nonspecific epidermal proliferation). The second group includes dermatologic disorders previously classified as dystrophies: psoriasis, allergic or irritant reactions, lichen simplex chronicus, and lichen planus. Because of shared morphologic characteristics, dermatologists call these disorders the papulosquamous dermatoses and include tinea and disorders also found on other areas of the body besides the

Another broad dermatologic category is the vesiculobullous diseases, which have blisters and secondary erosions or ulcers. Those with vulvar or vulvovaginal involvement will be discussed, as will ulcerative dermatoses resulting from systemic disease. Symptoms of vulvar disorders unrelated to vaginitis also include vulvar vestibulitis, vestibular papillomatosis, and essential (dysesthetic) vulvodynia.

Dermatologic diagnosis

Pruritus vulvae combines the subjective complaint of itching with the objective finding of leathery plaques (lichenification); visible scratch marks (excoriations) also confirm the diagnosis (Fig. 1, p. 1223). Burning is a "hands-off" symptom, and patients who do not itch may have minimal skin changes. The International Society for the Study of Vulvar Diseases defines vulvodynia as chronic vulvar discomfort, especially that characterized by the patient's complaint of burning, stinging, irritation, or rawness.2 Vulvodynia, a long-term rather than a short-term problem, has been linked in some cases to vulvar dermatoses, recurrent vaginitis (especially candidiasis), human papillomavirus, and dysesthesias.3

Contact and irritant dermatitis

Understanding the difference between irritant and allergic reactions helps in the choice of appropriate medications for the patient who claims she is "allergic to everything." Irritant reactions are common; true allergies are rare. The report of immediate burning or stinging when a medicine is applied to the vulva is typical of an irritant reaction; itching is unusual. Erythema and sometimes edema last for minutes to hours; vesicles do not form, and the affected skin may look dry or parched. Common irritants include soaps, medications (lidocaine and crotamiton), or ingredients such as alcohol and propylene glycol. Irritated, dermatitic skin can be soothed with sitz baths, Burow's compresses, and bland emollients (diaper ointment and vegetable shortening) for a few days. If the offending agent does not sting normal skin on other areas of the body, it can

often be applied to the vulva when initial reactions subside.

An allergic reaction signifies cell-mediated immunity. A familiar example is poison ivy, which causes itchy blisters on the skin of persons sensitized to the plant by prior exposure. The rash takes 48 hours to develop, affects skin wherever the allergen touched, and lasts for about 3 weeks. Treatment with cool compresses and potent topical steroid creams may help, but systemic steroids (30 to 60 mg of prednisone daily) will control severe outbreaks. Familiar medications that cause allergic reactions include topical diphenhydramine, neomycin, and ethylenediamine, which is a preservative in a popular nystatin-neomycin-triamicinolone combination cream.

Chronic dermatitis and lichen simplex chronicus

Chronic contact or irritant reactions itch, as do tinea or Candida infections; itching for any reason generates a nonspecific scratch response (Fig. 2, p. 1223). If scratching continues long enough, the result is lichen simplex chronicus, which is the objective finding in the subjective complaint of pruritus. Lichenification describes classic changes in the skin: thickened and leathery with enhanced skin-surface markings. Measures to , help the patient overcome the itch-scratch cycle include topical steroids to decrease inflammation and gradually flatten the thick plaques of lichen simplex chronicus and antihistamines for a soporific effect. Potent steroids (desoximetasone or fluocinonide) may be used for the first 4 to 6 weeks to control the inflammatory response, followed by a tapered dose of lower potency. Triamcinolone acetonide 0.1% may be used once or twice daily for as long as 2 months as lesions improve. (When lichen simplex chronicus lesions are dermatitic or "wet," a course of oral erythromycin or dicloxacillin speeds recovery.) Hydrocortisone 1% is excellent maintenance therapy for use "as needed." Localized thick plaques of lichen simplex chronicus on the vulva respond well to intralesional injection of triamcinolone acetonide suspension, 5 to 10 mg/ml. Side effects include epidermal and dermal atrophy and depigmentation, but dermatologists still prefer intralesional steroids over alcohol injection, which can cause tissue slough and scarring.

Side effects of topical steroids

The use of potent topical steroids should be limited to brief use for short-term problems; this avoids the many complications associated with long-term use. The best-known consequences include telangiectasias, easy bruisability, skin fragility, and striae formation. Striae are nonreversible and are particularly common in intertriginous areas, such as the upper thigh. The use of potent steroids on the vulva can cause "periorificial dermatitis," a rebound inflammatory reaction with erythema and a burning sensation that flares as the steroid

Table I. Differential diagnosis of the vulvar dermatoses

Condition	Clinical appearance	Diagnostic test	Therapy
Psoriasis	Red plaques with silvery scale; also on knees, elbows, scalp; nail pitting	Clinical appearance; cutaneous biopsy	Topical steroids (triamcinolone 0.1%); systemic antimetabolitics Rx if severe
Seborrheic derma- titis	Scaling/erythema; also on eyebrows, nasola- bial folds, hairline, occ axillae	Clinical appearance; KOH preparation of scale negative	Dandruff shampoos, hydrocortisone 1% cream
Dermatophyte (tinea cruris)	Annular plaque with central clearing and peripheral scale; KOH—>hyphae	KOH preparation of scale positive	Topical imidazole creams bid until clear for 1 wk
Chronic dermatitis (contact or irritant)	Often eczematous and oozing; may involve congruent areas, eye- lids; may generalize	Careful history and patch testing if indicated	Cool compresses, Crisco or hydrocortisone 2.5% ointment, no allergens
Lichen simplex chronicus	Thick, furrowed vulva; other common sites are ankle, arm, or nape of neck	Cutaneous biopsy	Triamcinolone 0.1% ointment for 4-6 wk; rule out vaginal <i>Candida</i>
Lichen planus	"Purple polygonal pap- ules and plaques," lacy white pattern or erosions on oral and vulvar mucosa; wrists, shins common	Cutaneous biopsy	Topical steroids: cream or suppositories
Lichen sclerosus	White, wrinkly; usually only vulva, anus ("keyhole" pattern); dermis thick, epidermis atrophic; occ patchy on trunk	Cutaneous biopsy	Topical testosterone propionate 2% in petrolatum or Aquaphor bid; topi- cal progesterone in children

KOH, Potassium hydroxide; bid, twice daily.

is withdrawn (Fig. 3, p. 1223). A cycle of symptomatic vulvar dermatitis can be established as the patient treats the erythema and discomfort with the same potent topical steroids that started the problem. A combination cream of clotrimazole (antifungal) and betamethasone dipropionate (topical steroid) has been a frequent offender in the development of periorificial dermatitis, and it should not be used for chronic vulvar dermatoses.

Dermatoses

Most vulvar eruptions are "papulosquamous" (thick and scaly) dermatoses, and they are the most common skin diseases in the general population. Erosions or even ulcers may result from excessive scratching, but these are secondary to excoriation and do not change the categorization of the disease process. If the patient denies scratching and describes blisters or primary ulcers, she may have a vesiculobullous disease. The differential diagnosis of red, scaly, cutaneous plaques includes psoriasis, seborrheic dermatitis, lichen simplex chronicus, lichen planus, lichen sclerosus, and dermatophyte (tinea) infections (Table I).

Psoriasis. The most common (vulgaris) pattern of psoriasis on the body is red plaques with thick silverywhite scales on the scalp, knees, elbows, and sacrum.

On the vulva, the appearance varies from moist greyish plaques on the labia majora to glossy red plaques without scale in skin folds. Topical hydrocortisone is safe for prolonged use, even in pregnancy, and genital lesions usually respond well. For painful fissuring and maceration, short-term intermittent (no more than 2 to 3 weeks) use of fluorinated steroid creams may reduce inflammation and encourage healing.

Tinea. Chronic tinea cruris is uncommon in women; tinea versicolor is more frequent than classic dermatophyte infection. Tinea lesions can take many forms; thus any scaly eruption on the vulva should be scraped for a potassium hydroxide examination. Topical antifungals are effective in all but the most widespread eruptions or deep follicular infections. The imidazole compounds (clotrimazole and miconazole) are excellent; nystatin and terconazole, a triazole, are indicated only for *Candida* infections. Twice-daily treatment is best (rub in well); it should continue for at least a week after lesions clear. For chronic tinea infections, systemic treatment with griseofulvin or ketoconazole should be considered; a 4- to 6-week course is effective in patients who are nonimmunosuppressed.

Lichen planus (erosive vaginitis). This papulosquamous disorder has two distinctly different expressions: smooth shiny pruritic flat-topped papules on the skin and white patches or erosions on mucous membranes. Lichen planus papules are characteristic and histologically distinctive, but mucous membrane erosions are nonspecific. Most patients have both cutaneous and mucosal lesions, but either type may appear in a given patient. Lichen planus is probably the major cause of chronic erosive vaginitis (Fig. 4, p. 1224).

The classic definition of lichen planus includes "five Ps": purplish, pruritic, polygonal papules and plaques. The polygonal outline is subtle, suggesting that the borders of small plaques tend to be defined by the crosshatch pattern of minor skin lines. Scaling is faint and more of a whitish-gray surface streaking (Wickham's striae), a lacy pattern often seen on the buccal mucosa. Lesions may line up along scars or scratch marks (the Koebner phenomenon, seen also in psoriasis). Additional lesions may appear on the volar wrist, lumbar back, medial thighs, ankles, and shins.

Topical steroids are the treatment of choice for lichen planus. High-potency preparations may be necessary, and intralesional triamcinolone is probably the best treatment for localized hypertrophic lichen planus. Erosive vaginitis may be controlled initially with potent topical steroid creams (clobetasol propionate, or desoximetasone) inserted vaginally each night for 1 or 2 weeks, with gradual tapering of the dosage, switching to hydrocortisone suppositories or creams as improvement occurs. Oral etretinate (Tegison) helps severe mucosal lichen planus, but teratogenicity and a half-life of many months contraindicate its use in women who are pregnant, who plan to become pregnant, or who may become pregnant during therapy.

Lichen sclerosus. Vulvar lichen sclerosus is a major genital dermatosis familiar to gynecologists as a symmetric "keyhole" pattern on the vulva. The sclerotic dermis is white with a thin atrophic epidermis that may be finely wrinkled or scaly (Fig. 5, p. 1224). Bruises, lacerations, and purpura are common on this fragile skin, especially when pruritus is present; blisters or ulcers may even develop in some lesions. The architecture of the vulva disappears as the labia minora resorb and efface; this finding may sometimes precede extensive vulvar whitening and is an early diagnostic sign. Symptoms of itching or burning are variable; they do not necessarily correlate with the size or severity of lesions.

Childhood lichen sclerosus is not uncommon; perianal or vulvar skin is typically pale and wrinkled on the surface, and petechiae and purpura make child abuse a possible diagnostic consideration. Vulvar lesions improve by puberty, but few clear completely. Hydrocortisone 1% cream or ointment alternated with bland emollients is frequently the only treatment necessary to control childhood lichen sclerosus; testosterone ointment should not be used.

Lichen sclerosus is the only vulvar dermatosis that sometimes responds to topical testosterone therapy (2%

testosterone propionate in petrolatum, formulated by the pharmacy). Prepubertal girls should be given progesterone ointment instead (100 mg of progesterone in oil mixed with I ounce of petrolatum). A treatment trial should be undertaken for at least 2 months of twice-daily application, which may be tapered to a maintenance dosage if a therapeutic effect is achieved. Many patients have no resolution of lesions; continued use of testosterone merely slows the progression of the disease and keeps involved skin from tearing. It is possible for symptoms to persist even while the skin's appearance improves, and topical steroids may be added temporarily for symptomatic relief of itching. Excisional surgery is not curative, because lesions can recur in grafted skin. However, introital narrowing can be surgically corrected, and topical therapy should be continued as soon as healing is complete.

Vesiculobullous diseases

Vesicles and bullae are the typical lesions for this group of dermatologic disorders, which can also be erosive on mucous membranes or the vulva. Differentiation between bullous diseases requires a biopsy for histopathologic examination and direct immunofluorescence, which requires a specific tissue fixative (not formalin). Other dermatologic disorders that may be bullous or erosive include acute contact dermatitis, lichen planus, and lichen sclerosus (Table II).

Erythema multiforme. Recurrent painful oral and genital ulcers are typical of erythema multiforme, which is usually associated with lesions elsewhere on the body, especially the palms and soles ("target" lesions). The most common association with recurrent erythema multiforme is a preceding flare of herpes simplex, but drug allergies are also a consideration. This condition may be very difficult to differentiate from Behçet's syndrome and aphthosis, both of which have episodic oral and genital ulceration.

Pemphigus. Pemphigus is an immune-mediated skin disorder in which there is destruction of the intercellular cement substance between epidermal cells. The result is fragmentation of the top layer of the skin with formation of blisters and erosions. Biopsy for immunofluorescence establishes the diagnosis, and high-dose systemic steroids (prednisone, up to 300 mg daily for widespread pemphigus vulgaris) may be required to bring about initial control. Immunosuppressive drugs are used for maintenance therapy.

Benign familial pemphigus. Benign familial pemphigus (Hailey-Hailey disease) is a rare autosomal dominant dermatosis; 70% of patients have a positive family history. A chronic, recurrent, erosive papular eruption in the groin (and other skin folds) persists despite a variety of palliative treatment regimens. Disease severity varies from patient to patient but typically waxes and wanes. Treatment is topical steroids and antibiotics

Table II. Differential diagnoses of vulvar erosions and blisters

Erosions or blisters	Diagnosis	Course	Patient age	Scarring	Oral	Body lesions
Dermatoses				•		
Erythema multi- forme	Histopathology	Recurs (HSV)	Any age	No	Yes	Palms and soles
Pemphigus	Immunofluorescence	Chronic	>Middle age	No	Yes	Yes
Benign familial pemphigus	Histopathology	Chronic	Postpuberty	No ·	No	Intertriginous
Bullous pemphigoid	Immunofluorescence	Chronic	Elderly	No .	No	Various ,
Linear IgA disease	Immunofluorescence	Chronic	Childhood `	No	No	Various
Lichen planus	Histopathology	Chronic	Postpuberty	Yes	Yes	Wrists, shins
Lichen sclerosus	Histopathology	Chronic	Any age	Yes	No	Rare
Infections						
Ímpetigo	Culture	Episodic	Any age	No ,	No	No
Herpes simplex virus	Culture	Recurrent	Any age	Sometimes	No	No
Herpes zoster	Culture	Episodic	More common With age, HIV	Frequent	No ,	Dermatomal
Systemic diseases					•	
Behçet's	Histopathology	Recurrent	Postpuberty	Common	Yes	Eyes, arthritis

for secondary infection. Immunosuppressant agents are of little value.

Bullous and cicatricial pemphigoid. More common in elderly persons, bullous pemphigoid lesions are the result of immune deposition at the dermal-epidermal junction at the basement membrane zone. Because there is an almost intact layer of epidermis over the blister roof, bullae are tense and last for days. Cicatricial pemphigoid (benign mucous membrane pemphigoid) typically localizes to certain areas, and the scalp or mucosae are common sites. Scarring is a dominant feature. Histopathologic studies and immunofluorescence should be performed. Control of bullous pemphigoid requires systemic steroids; alternate-day doses are usually less than 80 mg of prednisone.

Dermatitis herpetiformis. The confusing name of dermatitis herpetiformis reflects the appearance of grouped vesicles that may develop anywhere on the body. Immunofluorescence shows aggregates of immunoglobulin A (IgA) in the papillary tips of the dermis in biopsy specimens from anywhere on the skin. An often subclinical gluten-sensitive enteropathy is associated with dermatitis herpetiformis. Treatment is with dapsone or a gluten-free diet.

Pediatric vulvar disease

The need to recognize and establish an early diagnosis of abuse in cases of traumatic genital lesions in children is clearly a priority in preventing further damage. It is also important to recognize that purpura, erosions, and scarring can also be caused by genital cutaneous disease (Table II).

Lichen sclerosus. Lichen sclerosus has been reported as early as infancy and occurs often enough in pre-

pubescent girls that it should be a routine diagnostic consideration. Lichen sclerosus typically produces white scarring around the vagina, anus, or both, and lesions are easily traumatized. Itching lesions of lichen sclerosus may show purpura or lacerations from the patient's scratching, and pain on defectation or urination is a common complaint (for therapy, see above discussion).

Linear IgA disease. Linear IgA disease is named for the immunofluorescence deposition pattern of IgA on microscopic examination. Formerly known as bullous disease of childhood, blisters of this disease may resemble traumatic burns on the patient's skin, and clustered genital lesions suggest herpes simplex. Biopsy samples for histopathologic examination and immunofluorescence are diagnostic.

Bullous impetigo. Secondary infection of the genitalia with *Staphylococcus* or *Streptococcus* is common in pruritic dermatoses such as atopy. Lesions will be oozy and wet, sometimes with pustules. When secondary impetiginization occurs, the patient should be checked for an underlying dermatitis that must also be treated to prevent reinfection. Therapy includes topical measures (wet compresses and hydrocortisone cream) and systemic antibiotics (erythromycin and dicloxacillin).

Vulvar erosions secondary to systemic disease

In some cases, systemic diseases are associated with skin lesions that may involve the genitalia. These vulvar dermatoses are more likely to be encountered on a consultation service than in a general clinic (Table II).

Behçet's syndrome. Oral and genital ulcers alone do not establish the diagnosis or justify therapy for Behçet's syndrome. The diagnosis must be based on a

combination of three or more of the following clinical problems (including oral and genital ulcers): uveitis, cutaneous vasculitis, arthritis, meningoencephalitis, and cutaneous hyperreactivity to minor trauma (pathergy). Behçet's syndrome is often overdiagnosed; aphthosis or herpes simplex are more common causes of recurrent oral and genital ulcers.

Lupus erythematosus. About one fourth of patients with lupus erythematosus will have mucosal lesions, which are usually noticed during disease flares. Treatment of the lesions is symptomatic; systemic therapy is used to control the underlying condition. Recognition that the mucosal erosions in patients with lupus erythematosus may not be herpes simplex can spare her much distress.

Pellagra. Patients with poor nutrition may have dry scaly skin and erythema of mucous membranes, which is the result of multiple vitamin deficiencies and lack of essential fatty acids. The classic tetrad of pellagra (diarrhea, dermatitis, dementia, and death) results from niacin deficiency. Skin signs of pellagra include hyperpigmentation and peeling of intertriginous areas and erosive mucous membranes. The condition responds to a balanced diet.

Reiter's disease. Reiter's disease is a consideration in the differential diagnosis of chronic genital psoriasiform lesions. Mucocutaneous lesions may be pustular or erosive (keratoderma blennorrhagicum); they occur with recurrent symptoms of urethritis, inflammatory eye disease, diarrhea, and inflammatory arthritis. Reiter's disease is associated with HLA B-27.

Cancer

Extramammary Paget's disease. Extramammary Paget's disease is a distinct histopathologic entity that usually appears as a red, velvety, well-demarcated lesion with an eczematoid scaly surface. Because it resembles a benign nonspecific dermatitis, Paget's disease has typically been present for months to years at the time of diagnosis. The average age of patients with Paget's disease is 65 years; thus in this age group it is important to take biopsy specimens of lesions that are not responding to therapy, especially if they are asymptomatic. Excision is the treatment of choice for Paget's disease, with careful systemic evaluation to rule out underlying or associated adenocarcinoma.

Squamous cell carcinoma in lichen sclerosus. Lesions of lichen sclerosus may be the site of vulvar carcinoma in situ in older patients, probably because of chronic inflammation. Ulcerations developing in longstanding lesions of lichen sclerosus should be biopsied at different sites on the lesion border rather than at the base of the ulcer. Elderly patients are often reluctant to return for procedures; thus it is probably best to take biopsy specimens of suspicious lesions as soon as they are discovered.

Vulvar intraepithelial neoplasia (VIN). Condylomata acuminata are usually not difficult to recognize, but long-standing sessile lesions thought to be human papillomavirus (HPV) may be squamous cell carcinoma in situ or VIN, which is often a multifocal disease. VIN lesions may be condylomatous, eczematous, or ulcerated; coloration may vary from white to red or brown. Many patients with VIN mention only pruritus or a rough spot on the skin. Representative lesions should be biopsied to establish a diagnosis before destructive therapy is performed. It should be remembered that patients with multifocal disease can also have dermatitis. A biopsy specimen may show benign disease rather than malignancy.

Vulvodynia

As previously mentioned, vulvodynia is chronic vulvar discomfort with patients complaining of burning, stinging, irritation, or rawness. Candida is only one diagnosis associated with vulvodynia; vulvar dermatoses, papillomatosis, vulvar vestibulitis, and dysesthesias, such as pudendal neuralgia, must also be considered.

Vestibulitis. In the vulvar vestibule are the openings of the urethra and Skene's and Bartholin's glands. Close examination may also reveal the tiny pit-like openings of the minor vestibular glands, which scatter throughout the vestibule and concentrate in the posterior fourchette and in the groove at the base of the hymenal ring. Characteristics of vestibulitis are the patient's complaint of entry dyspareunia, discomfort at the opening of the vagina, and erythema and point tenderness discovered on palpation of the gland orifice with a cotton-tipped applicator.5

The significance of painful red vestibular glands is not entirely clear. Many women who have no problems with intercouse will mention pain on palpation of these glands during a routine examination. Inflammatory vulvovaginitis causes acute discomfort of vestibular gland openings, but this tenderness generally resolves with or soon after treatment of the infection. Chronic vestibulitis, however, persists for months or years, and patients experience not only entry dyspareunia but often have pain when they try to insert tampons. There must be factors other than the vestibular glands that affect this symptom complex, but more detailed study is needed.

Papillomatosis. Vestibular papillae are tiny fibrillary growths in the vestibule that are usually most numerous at the posterior introitus. They are a normal anatomic variant.4 Vestibular papillomatosis describes the presence of multiple papillae that may cover the entire mucosal surface of the labia minora. Papillomatosis can occur with human papillomavirus infection, but HPV is not proved in all cases. Normal women who have no clinical symptoms may have similar findings. Acetowhitening (application of vinegar or 3% to 5% acetic 1182 McKay
October 1991
Am J Obstet Gynecol

acid solution to the epithelium for 1 to 2 minutes) improves visualization of papillomatosis and parakeratotic changes. In the vulvar vestibule, papillomatosis and acetowhitening are both nonspecific findings of uncertain significance.⁵ In patients with symptoms of vestibular papillomatosis, expert colposcopic examination and acetowhitening should be used primarily for directing biopsies; histopathologic studies should be the basis for therapeutic decisions.

Essential vulvodynia. Essential (dysesthetic) vulvodynia typically occurs in elderly or postmenopausal patients who complain of diffuse and unremitting genital burning without evidence of vestibulitis or cutaneous changes. These patients describe pain patterns similar to postherapeutic neuralgia (postzoster neuralgia) and "glossodynia" (burning tongue), which suggests a problem with cutaneous perception either centrally or at the nerve root. A tricyclic antidepressant (amitriptyline) frequently brings relief at doses of 30 to 50 mg daily.

Summary

The multifactorial nature of the symptoms and physical expression of disease on the vulva complicates the evaluation and management of genital dermatoses. However, a few simple rules can help the clinician avoid the most common errors in diagnosis and treatment.

Because chronic itching usually leads to the development of lichen simplex chronicus, this diagnosis should not be assumed to occur as an isolated finding. One should always look for more than one potential cause for the complaint of itching or burning. Diagnostic tests, such as potassium hydroxide examination and cultures, should be performed routinely, and biopsy studies should be performed on any lesion for which the diagnosis is unclear. A diagnosis must always be made on objective grounds before a course of therapy is initiated. If appropriate therapy for a given diagnosis does not prove to be effective, it is best to reconsider the diagnosis before simply changing the treatment.

Understanding the chronic nature of skin disease is critical; management and not cure is usually the treatment goal. Few recurring skin diseases are curable but all are treatable; patients can be spared frustration when they receive the proper medication early in the course of the disease. The true definition of effective treatment for a dermatosis is whether routine application of a particular medication can control outbreaks or symptoms. Recurrence of a skin problem when medication is discontinued is not a treatment failure, but a sign that therapy has been appropriate and should be continued.

Topical therapy takes time to produce results; medications must be formulated carefully to penetrate a thick scaly skin barrier. It may be necessary to apply topical agents twice daily for as long as 1 week before symptoms begin to abate, and clearing of chronic lesions may take many weeks or months.

"Shotgun" therapy (use of different medications simultaneously or changing them after a few days) without a clear diagnosis is not a good management plan. Not only can medications interfere with one another, but the patient is discouraged by the expense and the feeling that her condition cannot be treated. She may become resentful and think that her treatment is experimental. The best maintenance therapy is often continuous use of bland emollients or mild topical steroids and reassurance that no infection or malignancy has been discovered. Fortunately, "psychosomatic disease" is a less common diagnosis than it was before objective findings in vulvodynia and dyspareunia were described. Careful examination of patients and selection of specific treatment plans can provide relief to many patients who had little hope of effective therapy in the past.

Vulvovaginal human papillomavirus infections: Clinical implications and management

Kenneth D. Hatch, MD

Tucson, Arizona

The past 2 decades have witnessed an alarming increase in the incidence of human papillomavirus infections. Clinically evident cases represent only a small portion of the infected population, because millions of people have subclinical or latent infection. Human papillomavirus infection is recognized as a precursor to malignancy. Thus it is important to treat clinically evident infection. Treatment is complicated by the ability of the virus to establish latent infection and the lack of an effective antiviral agent. At present treatment is limited to the destruction of obvious and intraepithelial lesions. (AM J OBSTET GYNECOL 1991;165:1183-8.)

Key words: Human papillomavirus infection, condyloma acuminata, laser therapy, α -interferon

During the past 2 decades there has been an alarming increase in the number of patients seen with human papillomavirus (HPV) lesions. Part of the increase is a heightened awareness of the several manifestations of HPV growth; however, the number of cases of condyloma acuminatum has increased 10-fold during the past 15 years, and it is now the most commonly diagnosed sexually transmitted disease in the United States. Moreover, the number of patients with clinically overt disease is just the tip of the iceberg that includes virtually millions of sexually active adults with subclinical or latent infections. DeVillers et al. reported that 10% of more than 9000 West German women with normal Papanicolaou smears tested positive for HPV 16 by filter in situ hybridization. Approximately 30% of these women had a sustained positive test, whereas the others had a subsequent negative test. Some patients had a negative test result on the first screening but had positive findings on a subsequent screening. This suggested that HPV exposure occurs intermittently and that HPV may be a commensal, much like Candida albicans or Staphylococcus aureus. Other countries have reported similar incidences of asymptomatic HPV. Kjaer et al.² reported as high as a 13% rate in Greenland and Denmark. Toon et al.3 reported an 11.5% rate in the United Kingdom. In the United States, Becker et al.4 reported an 8% rate among women attending a university student health service and a 25% rate among women attending a sexually transmitted disease clinic.

Management

To treat HPV infection of the anogenital tract successfully, the physician must have a basic knowledge of the anatomy of the skin on which the virus is growing. Warts located on the keratinized, hair-bearing areas of the skin tend to produce thick keratin growths. These growths are more resistant to topical chemodestructive therapy than are mucosal lesions, which are softer and more vascular and therefore allow better penetration of the topical agents and greater efficacy. The pilosebaceous appendages of the hair-bearing areas may be infected with HPV and allow regrowth of the wart from the hair shafts and sweat glands. Fortunately, infection does not usually penetrate deeply into these appendages, and destruction directed to the surface is often successful. The physician must also recognize that latent virus is present in normal-appearing skin around the obvious lesion. Regrowth from this latent virus requires weekly reevaluation and treatment until the host has been able to effect its immune response and further expression of the virus is halted. For this reason, the simplest forms of treatment are the best when the patient is in this productive phase of HPV infection.

The simplest treatment is either bichloroacetic acid or trichloroacetic acid. A 50% to 85% solution is used; the water content of the tissues treated neutralizes these dessicant acids. Thus keratinized lesions, which contain little water, are more resistant to the acids. Mucosal lesions are the most suitable warts for treatment. Because the acids contain no toxic agents to absorb, they may be used in the vagina and on the cervix. They are also safe for use during pregnancy.

Laser treatment

For acid failures, the CO₂ laser has gained widespread popularity in the treatment of HPV. When cou-

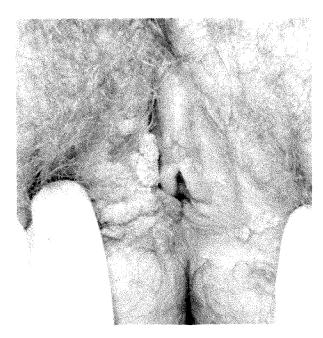

Fig. 1. A 20-year-old woman with recurrent condyloma after multiple treatments including laser treatment.

pled with the operating microscope (colposcope), it allows the surgeon to identify and destroy both microscopic and macroscopic HPV. By learning to identify the dermatologic surgical planes, the surgeon can avoid damage to the underlying dermal architecture and thus avoid scarring.

Tissue destruction from the laser occurs from both immediate vaporization and delayed tissue necrosis. The former can be controlled by observation of the surgical planes; the latter can be controlled by keeping the power density above 750 W/cm³. Power densities below this level lead to excessive tissue necrosis.

Laser vaporization should not be used as initial therapy for patients who are still in the proliferative phase of rapid epithelial and papillary growth formation. It is best used with patients who have developed resistant, thick keratotic lesions unresponsive to local chemical therapy. When used in this manner, the remission rate is approximately 85%. When possible, outpatient treatment with local anesthetic is preferred. The intradermal injection of local anesthetic helps produce a water barrier at the dermoepidermal junction and aids in identifying the dermatologic planes.

The wart produces a thickening of the normal epidermis. The goal is to vaporize this thick epidermal outgrowth without damage to the papillary dermis below. A high-power density should be used, with frequent removal of charred debris by wiping with a wet gauze. The dermoepidermal junction can be recognized by an intact, shining surface with microscopic papillary dermis. Normal-appearing skin around the

wart for a distance of 1 cm should be "flashed." This step is accomplished by rapid movement of the laser beam, which produces a typical crackling sound. The surface of the skin blanches and bubbles appear underneath. This layer is easily wiped away, and the papillary dermis can be observed. Cooling the vulvar skin with cold, moist gauze aids in limiting thermal injury. After surgery the patient's laser wound is cooled for 24 hours and is then treated with topical silver sulfadiazine. Healing takes place in 10 to 14 days without scarring.

The wart that involves skin appendages, such as hair follicles or sebaceous glands, becomes more difficult to treat. The skin appendages penetrate the papillary and reticular dermis, which necessitates a third-degree burn to destroy the entire lesion to that depth. This burn takes several weeks to heal and results in scar formation. Small lesions (<5 mm) can be treated to this depth without significant cicatrization. Larger lesions, however, should not be treated this deeply. Because HPV infection generally involves the superficial portion of the skin appendages, lesions in these patients can be vaporized to the second surgical plane and still preserve the reticular dermis, leaving a foundation over which reepithelialization can take place quickly from the hair follicles.⁵ This plane is recognized by the roughened, yellow base visible through the microscope. Although the entire hair shaft or sebaceous gland is not destroyed, the success rate is satisfactory. Interferon therapy after laser treatment further improves the success rate (Figs. 1 through 4).6 Treatment of warts through the third surgical plane may cause cicatrization and is not advised.

α-Interferon

In 1957 Isaccs and Lindermann⁷ first described interferons as endogenously produced cytokines that protect cells against viral infection. The three major types of interferon are α , β , and γ . α -Interferon is the agent currently used to treat condylomata acuminata. Since 1980, recombinant deoxyribonucleic acid technology has been used to mass produce α -interferon, which has facilitated the completion of clinical trials. Vance et al.8 reported the first randomized controlled trial of interferon. Patients had a single wart injection three times a week for 3 weeks with either 106 U, 105 U, or a placebo. They were then observed for an additional 9 weeks. Of the patients who received the 106 U dose, 53% had complete clearing of their lesion compared with 17% of the placebo groups. Most responses occurred between 4 and 9 weeks despite the fact that injection was stopped at 3 weeks (Fig. 5).

Eron et al.⁹ reported a randomized, double-blind trial in which patients had as many as three warts injected with 10⁶ U per wart three times a week for 3 weeks.

Fig. 2. Laser vaporization at 1000 W/cm².

Fig. 3. Papillary dermis of the first surgical plane is seen after epithelium is wiped away.

Complete responses occurred in 36% of these patients compared with 17% in the placebo group. In this study, an open-label phase was used in which those patients who received interferon and responded but whose disease then progressed were retreated with interferon. Their response rates were similar to those of the originally treated group. This finding indicates that patients who respond to interferon and then suffer a recurrence can be expected to respond when treated again. It also suggests that treatment may be required beyond the currently recommended 3 weeks.

The use of interferon after laser vaporization has also been successful in reducing recurrences.6 At the site of laser treatment, 106 U of interferon is injected three times a week until complete healing has occurred. This treatment is particularly helpful in the treatment of patients whose warts are on the hair-bearing areas of the skin. Interferon is effective in eliminating regrowth of warts from the hair follicles, allowing the laser vaporization to be limited to the first surgical plane.

A 27-gauge insulin syringe is used for injection, because these syringes have no hub and all the medicine

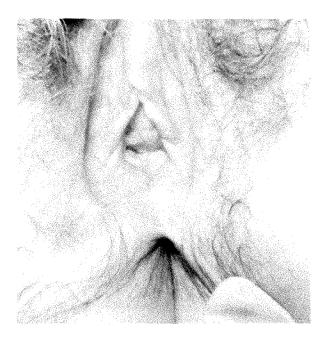

Fig. 4. Appearance of patient 10 weeks after laser treatment with adjuvant interferon used for 4 weeks to reduce recurrence.

is delivered. The injection is placed intradermally at the base of the wart or into the wart itself. The major side effect of interferon is a flulike syndrome. This occurs 2 to 4 hours after injection and abates 4 to 6 hours later. This syndrome responds to acetaminophen and decreases with each treatment so that patients hardly notice it after the first week. Hematologic effects at the 106 U, three times weekly dose are negligible, and a complete blood cell count is not routinely performed. Patients receiving 3×10^6 U three times weekly may experience leukopenia in the 3000 cells/mm³ range; a complete blood cell count should be obtained if treatment goes beyond 3 weeks. The leukopenia is reversible on cessation of treatment. Mild elevations in liver enzyme levels have been observed but are not of clinical significance, and monitoring is no longer performed.

Interferon is also very useful as an adjunct to acid treatment for the large or still-proliferating warts. It reduces the total time of treatment and the rate of recurrence.

Clinical implications of HPV infection

It is now recognized that genital neoplasia is a continuum that begins with HPV infection. Attempts have been made to correlate morphologic findings, HPV type, and histologic appearance. The implications of these studies are that the distinction between flat condyloma and true cervical-intraepithelial neoplasia (CIN) has important clinical relevance, and therefore

the management of these lesions may be different. Willet et al.¹⁰ studied 71 patients with lesions ranging from flat condyloma to CIN and analyzed them for HPV type and the presence or absence of abnormal mitotic figures. HPVs 6 and 11 were found in 5 of 25 of the flat condylomas and in 0 of 14 of the CIN IIIs. Conversely, HPV 16 was found in 12 of 14 of the CIN IIIs and in 6 of 25 of the flat condylomas. Abnormal mitotic figures were found in 4% of flat condylomas, 13% of CIN I lesions, 39% of CIN II lesions, and 64% of CIN III lesions. Because of the difficulties in histologic discrimination and similar distribution of HPV types in low-grade lesions, they proposed that the flat condyloma and CIN I be grouped together and the term "flat condyloma" be abandoned. The Bethesda System¹¹ of cytologic classification also recognizes that these lowgrade lesions are hard to separate and groups them together. The investigation of HPV subtypes in invasive cervical cancer has disclosed that HPV 16 is found most commonly in squamous keratinizing tumors, whereas HPV 18 is found more commonly in adenocarcinomas and poorly differentiated squamous carcinomas. In a study by Wilcynski et al.12 of 41 cervical carcinomas, HPV 16 was found in 77% of the large-cell keratinizing tumors and in one of eight adenocarcinomas. Conversely, HPV 18 was identified in four of eight adenocarcinomas and in two of 13 large-cell keratinizing tumors. Patients with the large-cell nonkeratinizing tumors are the highest percentage in whom no HPV deoxyribonucleic acid was identified (9/16). Barnes et al.13 studied 30 patients with invasive cervical carcinoma and found that five of six HPV 18-associated tumors were grade 3 compared with 7% of HPV 16-associated tumors. The HPV 18-infected group was significantly younger (average of 37 vs 49 years of age) and had a higher incidence (60% vs 36%) of lymph node metastases. This suggests that HPV 18 may be associated with a more aggressive form of cervical cancer. Kurman et al. 4 reported on overrepresentation of HPV 18 in invasive cancers when compared with CIN and suggested this as evidence that HPV 18 lesions may progress rapidly through the CIN stage to invasive cancer.

Vulva intraepithelial neoplasia (VIN) and invasive vulvar cancer are also associated with HPV. Twiggs et al. ¹⁵ studied 25 patients with either Bowen disease or VIN; 19 tested positive for HPV and 11 tested positive for HPV 16. Patients who were HPV positive were younger and had multifocal disease with involvement of several sites in the genital tract compared with those who tested negative for HPV. Buscema et al. ¹⁶ studied 86 patients with condyloma acuminatum, VIN, and invasive vulvar cancer. HPVs 6 and 11 were found in 77% of those patients with condyloma acuminatum and in 0% of those with VIN, whereas HPV 16 was found in 81% of those persons with VIN, 66% of those with

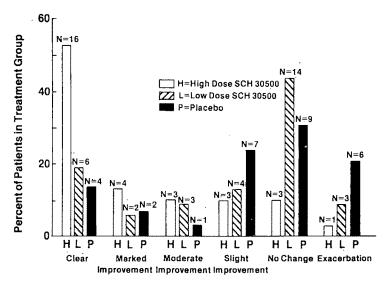

Fig. 5. Distribution of patients in disease status after treatment with 1 million U of α -interferon compared with 100,000 U and placebo. (From Colposcopy and Gynecologic Laser Surgery 1988;4:187-96.)

invasive cancer, and 12% of those with condyloma acuminatum. HPV 18 was found in a low number in both groups. Progression to invasive cancer from VIN has rarely been reported. Generally these patients have immunosuppression disorders, are over age 50 years, or both. Planner and Hobbs¹⁷ examined 335 patients by colposcopy who had cytologic evidence of HPV. They found that 94% had cervical infections, 82% had vaginal infections, and 44% (148) had vulvar disease. Of these 148 patients, 7.4% (11) had VIN. Two patients' disease progressed to VIN III, and one (age, 25 years) developed invasive cancer.

The most common mode of HPV transmission is sexual contact. Fifty percent of male consorts of women with condyloma acuminatum demonstrate visible lesions. Colposcopic examination after the administration of 5% acetic acid usually reveals a subclinical infection in an additional 24%.18 Barraso et al.19 reported 294 men who were consorts of women with flat condyloma acuminatum of the cervix. They found that 41.1% had HPV penile lesions and 3% had intraepithelial neoplasia. In addition, 186 men who were consorts of women with CIN were examined, and 36% of these men had penile intraepithelial neoplasis. Gal et al.20 found HPV lesions in 76% of the male consorts of women with HPV lesions with (n = 31) or without (n = 82) CIN. HPV typing of the male-female lesions disclosed homology in 60% of HPV 6 and 11 lesions and in 17% of HPV 16 and 18 lesions. Despite treatment of both men and women, a 10% recurrence rate occurred in the group with HPVs 6 and 11 and a 35% recurrence rate in the group with HPVs 16 and 18. This suggests that transmission by simple sexual contact is not the entire problem and barrier techniques, such as condoms, may not be effective.

HPV infection is increasing at an alarming rate. Its association with malignancy of the lower genital tract is the impetus to treat patients with infection. The ability of the virus to establish a latent infection and the lack of a specific antiviral agent make this a difficult task. Until such time as an antiviral agent is developed, the goals of treatment should be eradication of the obvious HPV infection and the intraepithelial lesions.

Mycotic vulvovaginitis: A broad overview

Benson J. Horowitz, MD

Hartford, Connecticut

The incidence of mycotic vulvovaginitis is rising dramatically in the United States mainly because of an increase in infections caused by *Candida* species. Accurate diagnosis depends on culture techniques that will yield correct identification of fungal pathogen(s). Recurrences are common and require culture specimens from sexual partners and appropriate antifungal therapy. The imidazoles and more recently the broader spectrum triazoles are used for vaginal therapy. (AM J OBSTET GYNECOL 1991;165:1188-92.)

Key words: Mycotic vulvovaginitis, Candida species, fungal infections, antifungal agents

In the United States alone, 13 million cases of mycotic vulvovaginitis occur annually. During the past decade, the population of women 18 years of age and older has increased approximately 13%, whereas the number of prescriptions written annually for vulvovaginal candidiasis has increased more than 53%. In the United Kingdom, the number of cases of vaginal candidiasis reported in sexually transmitted disease clinics has increased from 21,000 in 1972 to 38,000 in 1982. Candida species were the third most frequently reported pathogens associated with nosocomial bloodstream infections as reported by Horan et al. in the National Nosocomial Infections Surveillance System between January 1985

and August 1988. This report indicates that in 1984 Candida was ranked eighth, thereby indicating a trend toward increasing prevalence of Candida. Interestingly, in the 1988 National Nosocomial Infections Surveillance System report, 35% of the yeast species were non-albicans.

These data and the daily experiences of clinicians affirm the impression that human mycoses in general and vaginal mycotic disease in particular are on the rise. The advent of immunosuppressive disease created iatrogenically with the use of cyclosporine in patients undergoing transplantation, pathologically in patients with acquired immunodeficiency syndrome, or chemotherapeutically in patients with cancer creates premature death not by the disease process but by the opportunistic infection by the lowly one-celled fungus—the yeast. It is evident that knowledge of and familiarity with fungi are of the utmost importance to physicians of all medical disciplines. As the human ex-

Classification

The study of fungi has been complicated by their attempted inclusion into the plant or the animal kingdom. This confusion was created by the fact that some fungal processes are shared by both plants and animals. The dilemma was remedied by the establishment of a third kingdom called the kingdom of fungi. As a result, there are now three kingdoms: plants, animals, and fungi.

The taxonomic classification of the kingdom of fungi as it pertains to human disease is in the form phylum Deuteromycota, form class Blastomycetes, and form family Cryptococcaceae. The six genera of the form family Cryptococcaceae are of particular interest to the practicing vulvovaginologist. These genera are Cryptococcus, Malassezia, Rhodotorula, Candida, Trichosporon, and Geotrichum. Members of all of these genera have been found in women with vulvovaginal complaints. The most important members of the genus Candida in human clinical disease are: C. albicans, C. tropicalis, C. glabrata, C. krusei, C. parapsilosis, C. pseudotropicalis, C. lusitaniae, and C. rugosa. C. stellatoidea has recently been incorporated in C. albicans, and Torulopsis glabrata was renamed C. glabrata.4 Currently the most frequent and important systemic and vaginal yeasts are C. albicans, C. tropicalis, C. glabrata, and C. parapsilosis.

In a random study population of women with vulvovaginitis caused by a fungus,5 C. albicans was found in at least 65% of patients. Twenty-three percent of these patients harbored C. tropicalis. In this study, Cryptococcus ungulaticus, Trichosporon beigelii, and Saccharomyces cerevisiae were also found. Three percent of the study population with vulvovaginitis had dermatophytes. In a study of 2184 isolates from 18 studies from 1963 to 1987,6 C. albicans was cultured in 84.2%, C. tropicalis in 5.3%, and C. glabrata in 5.5% of patients.

Morphology

Recognition of the morphology of fungal species leads to proper diagnosis. There are only three anatomic structures that the clinician must recognize for diagnostic purposes: the pseudomycelia, the blastospore, and the chlamydospore. The pseudomycelia is the long filamentous form with its arborization of branches. It is called a pseudomycelia because of its lack of segmentation. The blastospore is the collection of small refractile bodies resembling a group of glass beads, and the chlamydospore is a terminal birefractile sphere at the end of a pseudomycelia. Recognition of these structures is necessary to achieve therapeutic goals. Emphasis on filamentous forms versus budding forms is misplaced because depending on environmental conditions, the organism will assume either of these two anatomic structures. When the yeast assumes the filamentous form, candidal adherence is facilitated. The three candidal organisms of greatest prevalence, namely, C. albicans, C. tropicalis, and C. glabrata, are easily recognized by their morphology. The albicans organism consists of pseudohyphae, blastospores (blastoconidia), and chlamydospores (chlamydoconidia). The tropicalis organism has no terminal chlamydospore, and the organism appears as great clusters growing on a central stem. The glabrata organism contains no pseudohyphae and no chlamydospores but is only a collection of blastospores.

Biochemistry

The most important biochemical characteristics of yeasts are their ability to ferment and assimilate sugars. The specific sugar that is metabolized has been used as the traditional method of fungal identification. The tools of molecular biology offer more exact methods of identification; however, for the average clinician the former method is sufficient. The fermentation and assimilation patterns are easy ways to identify the particular species. Both five- and six-carbon atom sugars are metabolized. The efficiency of a yeast to convert sugars to carbon dioxide and ethanol cannot be duplicated by the chemist. Because of this, the brewing industry relies on the biochemical processes of the yeast in an anaerobic environment to make alcohol, and the baking industry relies on this process in an aerobic environment to leaven baked goods by the production of carbon dioxide.

In a study⁷ that used sugar chromatography,⁷ those cases of vulvovaginitis labeled recurrent or culture positive revealed a greater amount of sugar in the urine than in normal persons. From this work it was deduced that the amount of sugar substrate consumed by a woman was of importance in the continuation and persistence of vulvovaginal infections.

Pathophysiology and pathogenicity

The familiar reddening of the vaginal and vulvar tissues and the recognition of satellite lesions caused by candidal infection are easily recognized by the clinician. The pathogenesis of the reddening and the symptoms of itching, burning, and discharge are probably produced by the production of alcohol in the microaerophilic environment of the vagina. Other factors affecting the pathogenicity of the organism are sugar substrates;7 dressing patterns,8,9 antibiotic therapy,10,11 activated reservoirs, 12-14 antifungal bacterial factors, 15 adherence phenomena,16,17 immunologic hypersensitivity, 18-20 fungal species,5 and certain forms of contraceptives.21

Transmission of candidal organisms from a male partner to the vagina has been studied by several authors. 14, 22, 23 In a recent study of the male consorts of women who had culture-proved *Candida* vulvovaginitis, 33% had the same organism in their oral cavities, 36% in their rectal cavities, and 15% in their ejaculates. Results of prostatic cultures were negative; however, results of ejaculate cultures were positive. This suggests that the organisms reside in the seminal vesicles where fructose is abundant. In contrast, consorts of women without symptoms had negative results for cultured *Candida* orally and in their ejaculate. 14

Laboratory identification

The techniques for laboratory diagnosis of yeast infections have been simplified, and rapid diagnostic kits are available. Sabouraud's dextrose medium impregnated with chloramphenicol used as the basic culture medium for *Candida* is easily obtained from local suppliers. Thayer-Martin medium, an anaerobic culture medium used predominantly for the isolation of the gonococcus, may support the growth of yeast when Sabouraud's dextrose medium fails. After 5 days of incubation in ordinary conditions of light and temperature, the white mucoid colonies can be transferred to species identification kits. Incubation at 37° C with serum produces "germ tubes" (the Reynolds-Braude phenomenon). Germ tubes are produced by *C. albicans* and some species of *C. tropicalis*.

Just as it is necessary to identify bacteria because the individual characteristics of these organisms are important for therapy, so is it true of yeasts. Each of these yeasts have different characteristics. The nature of these differences will be of importance in the design of antifungal preparations and in the spectrum of recurrent and relapsing disease.

The use of culture kits provides the clinician with irrefutable evidence of a mycotic infection, indicates the exact species of the organism, provides information concerning sexual transmission, and delineates reservoirs. This information is essential in the treatment of recurring and relapsing disease.

Cell wall biochemistry and modes of action

Yeast organisms have a unique cell wall, and the biochemical pathways in the cell wall are important for its integrity. These pathways are more similar to those of the plant kingdom than to those of the animal kingdom. The sterol pathways proceed from squalene through squalene 2,3 oxide to lanosterol, and on to ergosterol. Antifungal agents are specifically designed to interfere with these biochemical pathways. The enzymes of the cytochrome P-450 group are particularly vulnerable, and this accessibility provides an opportunity for pharmacologic effectiveness. Yeast cell walls also consist of

the polysaccharides glucan, mannan, and chitin, protein, lipids, and in some cases capsular polysaccharides.²⁴ Mannoproteins are the main antigenic components of the cell wall.

Yeast cells also contain estrogen receptors in the cell wall. Yeasts do not proliferate without estrogen support.

Pathogen susceptibility

In 1972 Van Cutsem and Thienpont,²⁵ testing miconazole's effectiveness against various species of yeasts, found that it took 10 times more miconazole to eradicate *C. tropicalis* and *C. glabrata* than *C. albicans*.²⁵ Takada et al.²⁶ reported that the minimum inhibitory concentration of imidazole antimycotics, including econazole, miconazole, and clotrimazole, against *C. glabrata* was two to four times higher than that against *C. albicans* isolates. These data unequivocally support the concept that all species of *Candida* are not the same and that recurrence and relapse may be from ineffective concentrations of antifungal agents.

Aspects of selection

The prevalence of non-albicans species in the 1970s, as tabulated in nine studies, approximates 9.9%. In the 1980s, seven studies revealed a prevalence of 21.3%. During this same period, the incidence of *C. glabrata* increased from 4.6% to 6.7%, and *C. tropicalis* increased from 1.3% to 8.2%. Data from clinical studies demonstrated an increase in non-albicans species from 9% in 1971 to 14% in 1987. The increase in *C. tropicalis* has been the most dramatic.

Although the exact cause of this non-albicans selection is unknown, there is some evidence that antifungal therapy itself may be the cause. Redondo-Lopez et al.27 concluded that most patients in whom C. glabrata was isolated were treated previously with a multitude of antifungal agents and that iatrogenic factors select for the presence of C. glabrata. Kerridge and Nicholas²⁸ found that strains of C. glabrata were more resistant to the imidazoles than were C. albicans. They noted that C. glabrata is haploid and C. albicans is diploid. This may account for increased drug resistance. Horowitz et al.5 and Merz and Sanford²⁹ described strains of C. tropicalis with the ability to forego the $14-\alpha$ -demethylation pathway in the cell wall, making these organisms resistant to imidazole therapy. All these data suggest that the non-albicans species are more resistant to imidazole and polyene macrolide therapy and that the therapy itself created the non-albicans selection.

The second theory involves the use of shorter courses of imidazole therapy. Support for this theory can be found from the history of such infections in patients with neutropenia. Increased numbers of systemic infections caused by *C. tropicalis*, *C. glabrata*, and other

non-albicans species were related to the routine use of prolonged, low-dose prophylactic polyenes and imidazoles to prevent oral and systemic candidiasis. Takada et al.33 described replacement of initial C. albicans vaginitis with C. glabrata in patients treated with clotrimazole.

Therapy

Commonly used products that eradicate fungal infections are the imidazoles and polyene macrolides. These products interfere with the sterol chemistry pathways in the cell wall of the fungal cell. The imidazoles interfere with the $14-\alpha$ -demethylase enzyme in the conversion of lanosterol to ergosterol. Interference is also noted in side-chain cleavage, the desmolase reaction, and the 11B-hydroxylase enzyme. Polyene macrolides, such as nystatin, katamycin, and amphotericin B, also interfere with the formation of ergosterol. The general formula of an azole antimycotic is a pentene ring containing two nitrogen atoms and three carbon atoms to which side chains are added. The configuration of the side chain determines the nature of the imidazole compound. Examples of the compounds are miconazole, clotrimazole, tioconazole, ketoconazole, and butoconazole.

Not all imidazoles are equally effective against all species of yeasts. For example, C. tropicalis and C. glabrata are 10 times less sensitive to the action of miconazole than is C. albicans. Rhodotorula is particularly insensitive to the action of miconazole. For this reason, other agents have been devised and they fall into two classes: a new azole antifungal, the triazole, and the pyrimidines.

The development of the triazole compounds, specifically terconazole, addressed several of the difficulties of the imidazoles. A triazole is distinguished from an imidazole by the addition of a third nitrogen atom in the pentene ring. Attached to the ring is a side chain. The configuration of the side chain is designed to make the compound more lipophilic for better cell-wall penetrability. Although both imidazoles and triazoles interfere with the cytochrome P-450 isoenzymes, the triazole is more potent. This potency increases the susceptibility of C. tropicalis and C. glabrata to terconazole. The biochemical configuration also creates enhanced antifungal action at lower pharmaceutical concentra-

Although azole compounds interfere with cytochrome P-450 processes both in the fungal and mammalian vaginal cell, the chemical structure of the triazole makes it more selective. The ideal antifungal agent, one that would interfere only with the fungal cell, is as yet unattainable; however, the enhanced selectivity of the triazole results in less vaginal irritation.34.35 Greater selectivity also allows for the development of compounds of greater concentration over shorter periods of time.

In contrast to the azoles, a pyrimidine is a six-carbon atom ring with four carbon atoms, two unsaturated bonds, and two nitrogen atoms. The pyrimidine acts in a totally different way in that it is converted to 5-fluorouracil when carried into the nucleus of the fungal cell where it actively destroys deoxyribonucleic acid and ribonucleic acid helices.

Recurrence and relapse

Recurrent and relapsing fungal infections cause great frustration to both patient and care provider. The management of these cases requires accurate diagnosis, which is crucial to appropriate therapy. Unless culture techniques are available, misdiagnoses will be frequent. Anaerobic lactobacilli, Mobiluncus, and Actinomyces can be mistaken for fungi. Recurrent fungal vulvovaginitis requires culture specimens from all partners14, 36 and appropriate fungal therapy directed at the source of the contagion. Vaginal therapy includes the imidazoles and more currently the triazoles; oral therapy, clotrimazole oral troches or nystatin pastilles; gastrointestinal candidiasis, nystatin tablets or powder or ketoconazole; and for ejaculate candidiasis, ketoconazole or fluconazole tablets. Prophylactic therapy with ketoconazole during the first 5-days of the menstrual cycle for six cycles or daily for 6 months was effective in preventing the symptoms of candidal vaginitis. However, symptoms returned after discontinuation of therapy.11

The continued application of current knowledge and the new therapies being developed will significantly aid the clinician in the quest for complete therapeutic success.
